Although ECT has been replaced by neuroleptics for the treatment of schizophrenia, there has been a recent reexamination of ECT as the primary treatment form for acute schizophrenia. Despite improvements in research design and increased clinical sophistication about schizophrenia, the overall results of these recent reports do not alter the early conclusions regarding ECT. Acute schizophrenic patients, particularly those with affective symptoms, respond rapidly to ECT. Relapse rates are still high, and chronic schizophrenic patients are still refractory to ECT. ECT can offer a temporary diminution of agitation and depression in all schizophrenic patients.

Studies Comparing ECT with Neuroleptics

After the early demonstrated efficacy of chlorpromazine and other neuroleptics for the treatment of schizophrenia, the obvious research task was to determine whether there was a differential efficacy between drugs and ECT. Two types of studies were conducted to answer this question. In the first type, ECT-treated patients were compared concurrently with patients receiving neuroleptic drug treatment. In the earliest study of this type (23), relapse rates were lowest for the ECT group (31%) compared with the insulin group (55% relapse rate) and the chlorpromazine-treated patients (91% relapse rate). Langsley and associates (24) found similar rates of improvement in a group of patients receiving ECT and those who received neuroleptic treatment. Fifty-two acutely ill schizophrenic patients who received 15–20 unmodified sessions of ECT were compared with 54 similar patients who received daily doses of 800 mg of chlorpromazine. The treatments were equal in improving affective symptoms, but chlorpromazine patients stayed in the hospital a shorter time, had less fear, and seemed to experience better relief of subjective distress. However, overall ratings by psychiatrists failed to differentiate between the treatments. Ayres (25) studied 263 schizophrenic patients who received one of several treatments. Only 9% of the 89 patients who received ECT alone needed rehospitalization; 20% of those who received chlorpromazine alone required rehospitalization. Ayres did not provide data on diagnostic types of schizophrenia, length or severity of illness, dose of chlorpromazine, or number of ECT sessions adminis-

tered. King (26) and Childers (27) also observed equal improvement rates in groups of acute schizophrenic patients who received ECT and those who received chlorpromazine. King found that ECT patients remained in the hospital longer than the drug-treated patients.

The second type of study consisted of retrospective comparisons of schizophrenic patients who were hospitalized before 1955 and therefore treated primarily with ECT and of similar patients who were hospitalized after 1955, when drugs were used. Achte and Apo (28) compared 427 schizophrenic patients hospitalized from 1950 to 1952 with 542 schizophrenic patients hospitalized from 1957 to 1959, after the introduction of neuroleptics. For the first-admission patients, 93%–95% were discharged within 2 years regardless of the type of somatic treatment received. Relapse rates were high in both groups. Within 3–5 years 39%–47% of the discharged patients had been readmitted. Pritchard (29, 30) conducted a similar study of 41 patients who were hospitalized from 1952 to 1953 and 47 patients hospitalized from 1956 to 1957. The first group which received ECT primarily, stayed out of the hospital longer after discharge than did the later group of discharged patients. Within the second group, ECT was judged slightly better than chlorpromazine in regard to patient outcome and follow-up. In both groups of patients, those with the shortest duration of symptoms had the best long-term results. Pritchard concluded, however, that "overall there is little true difference between groups in duration of stay in the hospital, or in readmission rates."

Rovere (31) studied 105 schizophrenic patients treated from 1950 to 1960, as neuroleptic drugs were being introduced. He noted that the recidivism rate, which was 70% in 1950, had decreased to 30% by 1960. He concluded that when drugs replaced ECT in the treatment of schizophrenia, the recovery period was shorter and recidivism was less frequent. A similar examination of the decade from 1953 to 1964 also revealed a trend toward shorter hospital stays as treatment methods shifted from only ECT in 1953 to only phenothiazines in 1964 (32). Lassenius and associates (33) compared three groups of first-admission schizophrenic patients who were admitted from 1944 to 1946, 1955 to 1956, and 1959 to 1960. ECT and other shock treatments, used as the primary treatment for schizophrenia between 1944 and 1946, were gradually replaced by drugs so that by 1959–1960 schizophrenic patients received mainly pharmacotherapy. The authors noted that drug treatment of schizophrenia has been associated with a reduction in hospital and other institutional care and consider pharmacotherapy to be the treatment of choice for this disorder.

Comment

These comparative and retrospective studies as a group suggest that schizophrenic patients in general respond similarly to ECT and pharmacotherapy. However, the studies contain many methodologic deficiencies that militate against a definite conclusion. Since great variability exists in diagnostic criteria, the number of ECT sessions, and the dosage of drugs used, as well as in the overall treatment philosophy of different institutions, these studies can only be said to approximate each other. However, it is possible to conclude with certainty that none of these studies suggests an overwhelming therapeutic advantage in acutely ill schizophrenic patients either for ECT or for pharmacotherapy. Furthermore, there seems to be no differential prophylactic effect on readmission rates between the treatments. However, drug-treated patients definitely have shorter hospital stays than do ECT patients.

The Camarillo Study

In 1965 May and Tuma (34) published the first of a series of reports concerning five treatment modalities for schizophrenic patients at Camarillo State Hospital (Camarillo, Calif.). The patients for their study were considered to be in the middle section of the prognostic range—they were neither extremely chronic nor so acutely ill that they were likely to rapidly improve regardless of treatment. The five treatment methods were individual psychotherapy, pharmacotherapy, pharmacotherapy combined with individual psychotherapy, ECT, and milieu therapy. The range of ECT sessions was 10–48, with a mean of 22. The primary neuroleptic used was trifluoperazine in the range of 10–40 mg/day, with an average daily dose of 25.5 mg. Many outcome measures were employed in a sophisticated research design in order to compare the five treatment modalities.

On all measures of immediate outcome, pharmacotherapy with or without psychotherapy was superior to ECT. Of the 48 patients treated with drugs, 46 (95%) were discharged within 1 year, compared with 42 (95.5%) of the 44 patients who received drugs combined with psychotherapy and 37 (78.7%) of the 47 patients who received ECT (35). May concluded that "it is reasonably clear that electroconvulsive therapy cannot be considered to be desirable as an alternative or serious rival to ataraxic drugs alone or to psychotherapy plus drugs." He hypothesized that ECT may be useful for the patient who develops serious toxic effects from drugs or who fails to respond to drugs alone or to drugs plus psychotherapy. It is possible, however, that some patients will respond only to ECT.

The original report (34) contained a 3-year follow-up which showed there were no statistical differences between the ECT patients and the two drug groups in the number of days spent in the hospital since original treatment. A subsequent study (36), which extended the follow-up to 5 years, found that drug-treated and ECT-treated patients seemed to spend approximately the same number of days out of the hospital after their

initial period of treatment. ECT patients may, in fact, do slightly better than the drug-treated patients. May and associates (36) concluded that it seems unlikely that the shorter stay of ECT patients represents a conscious avoidance of the hospital because of fear of the treatment. They did not present data to support this conclusion but stated only that the ECT was delivered under humane conditions. These follow-up findings led Shader (37) to hypothesize that if patients "are given ECT and reintegrate rapidly and therefore have brief initial hospitalization, this rapid pulling together helps patients to remain out of the hospital over the subsequent years."

Comment

The Camarillo study represents the most sophisticated and carefully controlled comparison of ECT versus other treatment modalities. The overall conclusion is that ECT has been justifiably replaced by neuroleptic medication. However, more than three-fourths of the mid-prognostic range schizophrenic patients who received ECT did respond to it, and as a group they remained out of the hospital as long as or slightly longer than drug-treated patients.

ECT Combined with Neuroleptics

Studies of the efficacy of ECT in combination with neuroleptics have attempted to determine whether the combination is more therapeutic than either treatment alone. In early studies (3) the two treatments seemed to enhance each other and produced as much as an 83% improvement in acute schizophrenic symptoms. Less ECT was used, which shortened the period of post-ECT confusion and thereby reduced the length of hospitalization. The treatment was also found beneficial for chronic schizophrenic patients (38–41). One of the more authoritative early supports for combined ECT and chlorpromazine treatment came from Rohde and Sargant (42). These authors routinely used 300 mg of chlorpromazine per day and ECT in the treatment of schizophrenia. The authors compared the combined results with those of ECT alone. At discharge, 69% of the ECT-alone patients still had evidence of schizophrenia, compared with only 29% of the combined treatment group. ECT in combination with chlorpromazine also decreased the length of hospital stay. The beneficial effects of the combination treatment were still apparent 2 years later, at which time 51% of the ECT group were still psychotic, compared with only 20% of the combined treatment group. This early enthusiasm for the ECT-drug combination was not unanimous (43, 44), and serious side effects were sometimes observed (45, 46). In reviewing the early literature, Grinspoon and Greenblatt (47) wrote that ECT plus phenothiazines caused an increased risk and that "one cannot be assured that combined therapy counterbalances what may be an increased risk."

Contradictory reports on the efficacy of combining ECT with antipsychotic drugs have continued to appear, although more authors have favored the combination. Childers (27) reported the results of a comparative study of four treatment methods for acute schizophrenia. Group A (N=20) received 12 ECT sessions and had a 55% improvement rate; group B (N=20) received 20 mg of fluphenazine per day for 30 days, with a 45% improvement rate; group C (N=20) received 1000 mg of chlorpromazine for 30 days, also with a 45% improvement rate; and group D (N=20) received 1000 mg of chlorpromazine as well as ECT, with an 80% improvement rate. No follow-up data were provided, nor were the criteria specified for diagnosis of schizophrenia or for improvement. Nevertheless, the authors concluded that the combination of neuroleptics and ECT "appreciably increases the percentage who attain a moderate or better improvement." There were no severe side effects from the combination.

Kelly and Sargant (48) and Roth and associates (49) noted immediate but transient improvement when ECT was combined with neuroleptics in the treatment of chronic schizophrenic patients. When compared with the results of ECT alone, however, both forms of treatment produced improvement followed by relapse, although the patient's hospital stay was shortened by the combination. Regestein and Roper (50), however, reported lasting remission of schizophrenia in an 8-month follow-up of a single patient. In a placebo-controlled study of chronic schizophrenic patients, Gambill and Wilson (51) found that ECT alone and drug (prochlorperazine) alone were far better treatments than the combination of ECT and active drugs, which was only slightly better than placebo.

Achte (52) retrospectively compared schizophrenic patients who were in Helsinki hospitals in 1960 and received ECT combined with neuroleptics with patients in 1950 who received ECT and other "shock" treatments. Although the discharge rate was higher for the combination treatment group, 5 years later the overall improvement rate was not statistically different from that of the earlier group. Nevertheless, Achte concluded that the prognosis for schizophrenia was more favorable in 1960 than in 1950.

Smith and associates (53) studied both acute and chronic patients and found an immediate favorable response with combined treatment. They compared 29 patients who received 12 ECT sessions plus 400 mg daily of chlorpromazine with 25 patients who received only 655 mg of chlorpromazine per day. Although both groups improved significantly, the combination group started to improve within 1 week and continued to improve faster than the drug group. Patients who received the combined treatment were discharged sooner and were readmitted less often. At 6-month or 1-year follow-up, there was no difference in the overall ratings of psychopathology between the two groups. Within 1 year after the original admission 8 (33%) of

the patients treated with drugs alone had been readmitted, compared with only 2 (10%) of the patients receiving combination therapy. These data strongly favored the combination of ECT and chlorpromazine for the treatment of schizophrenia.

The combination of drugs and ECT was found to be superior to each treatment alone in hospitals in Pakistan (54) and in Cairo (55). Weinstein and Fischer (56) unequivocally supported the use of ECT combined with drugs. They did not offer data, but presented four case histories and their extensive clinical experience to illustrate that the combination is particularly useful for patients who do not initially respond to ECT and then reach a plateau when treated with phenothiazines, like the patients of Witten (57). ECT "lifted" these patients off the plateau, reduced their need for high drug doses, and prevented relapse. Wessels (58) found unilateral and bilateral ECT combined with thioridazine to be equally efficacious for the treatment of acute schizophrenia.

Two critical reviews of the ECT-drug combination literature have been less enthusiastic about the therapeutic efficacy of combining the two treatments. Turek (59) criticized most reports as having an uncontrolled research design, variable number of treatments, heterogeneous diagnostic groups, and no follow-up. He concluded that more rigorous research is needed before the combination of ECT and neuroleptic drugs can be considered better than either treatment alone, particularly for chronic schizophrenic patients. Abrams (60) also reviewed the literature and commented that the data supporting the combination therapy are unacceptable and more research is needed.

Comment

Although early reports were enthusiastic, most of the later studies of the therapeutic efficacy of ECT combined with neuroleptic drugs have been equivocal. However, the excellent study of Smith and associates (53) strongly favored the combination. As with other treatment forms, the combination is most beneficial for acutely ill patients. Further carefully controlled studies are necessary before the combination can be judged superior to either treatment alone.

The Camarillo study suggests that neuroleptic drug administration after a course of ECT may be beneficial as a follow-up treatment for schizophrenic patients in the middle section of the prognostic range. The 3- and 5-year follow-up data were based on patients who received treatment of their physician's choice after the initial hospitalization with ECT. In practice, most patients who needed posthospital treatment probably received antipsychotic medication.

The potential toxicity of combining ECT and neuroleptic drugs is still unknown. Most later reports have stressed the safety of the combination. However, neuroleptic drugs that have hypotensive properties may augment the initial blood pressure drop after ECT. In older patients and those with vulnerable cardiovascular systems, a hypotensive crisis can result. Such an effect is more common when ECT is combined with reserpine, and this combination is no longer used.

REGRESSIVE AND MULTIPLE MONITORED ECT

Regressive ECT

An interesting modification of standard ECT procedure was introduced in 1946 as a possible treatment for chronic schizophrenia. This technique consisted of a large number of ECT sessions in a short period of time, usually 2–4 a day on a daily basis. The treatments were given until an acute brain syndrome was produced. In this state the patient was regressed and exhibited memory loss, marked confusion, disorientation, lack of verbal spontaneity, and slurred speech to the point of complete dysarthria. The patient was also apathetic, incontinent of urine and feces, often required spoon feeding, and occasionally was not even able to swallow, thus requiring tube feeding. Neurological signs included ataxia, spastic rigidity, hyperreflexia, occasional ankle clonus, and pathological reflexes (61). As the patient recovered, usually within 1–4 weeks, the symptoms of schizophrenia were often absent or diminished. The drastic nature of the treatment was justified by the treatment-resistant and hopeless nature of the chronic schizophrenic patient who had been hospitalized for many years. Most (although not all) early studies concluded that regressive ECT was useless with chronic schizophrenic patients.

After these negative accounts, regressive ECT was not discussed in the literature until 1973. Exner and Murillo (62, 63) then published a study of 32 chronic schizophrenic patients who received twice-daily ECT for 7 days a week to a total of 26 convulsions. They compared these patients with 21 process schizophrenic patients who received an unspecified dose of haloperidol for an equivalent period of time. Those treated with regressive ECT showed significantly greater improvement on all outcome measures including ratings of psychopathology, self-reports of symptom distress, family reports of patient behavior, and indices of social adjustment. Hospital discharge rates were higher among the regressive ECT patients. At 3-year follow-up these patients were doing remarkably well and significantly better than the drug-treated control group. Many of them were working and continuing to live out of the hospital. Spensley (64) criticized this study for using inadequate dosages of haloperidol, thus biasing the results in favor of the regressive ECT patients. The authors responded that not only did they use adequate doses of haloperidol, but the drug-treated patients also "manifested complete remissions and were discharged from the hospital" (65). This comment raises serious questions about the chronicity of the patients included

in the study. It would be very unlikely to have such a high remission rate for chronic schizophrenic patients, regardless of the treatment they received.

Multiple Monitored ECT

Multiple monitored ECT is a technique in which treatments are given several times a day, but at a lower electrical intensity than that used with conventional ECT. Seizure activity is monitored by EEG, while cardiac response is monitored by ECG. In the original description, Blachly and Gowing (66) reported the technique to be as safe as or safer than conventional ECT, with less memory loss. White and associates (67) noted that all 4 acute schizophrenic patients given this treatment had a complete remission, and 3 of 5 chronic schizophrenic patients improved. Bridenbaugh and associates (68) reported that 14 of 17 acutely ill schizophrenic patients given multiple monitored ECT had a marked improvement. During a follow-up period of unspecified length, there was no recurrence of illness. Abrams (69, 70) gave 38 patients with mixed diagnoses 4–6 sessions of multiple monitored ECT and reported that the side effects were not different from those of conventional ECT, although the course of treatment was accelerated in many cases. This technique therefore is considered to produce results at least as good as those of conventional ECT and uses less power to induce seizures (71).

Comment

Regressive ECT is a drastic procedure that has produced equivocal results. The majority of observations have been negative. Most of the favorable reports either have commented on the temporary nature of the improvement or lacked follow-up data. While Murillo and Exner's report (63) is provocative, it may have serious methodologic faults concerning the diagnosis of patients. It seems reasonable, therefore, to consider regressive ECT as an experimental procedure requiring further careful research evaluation.

Multiple monitored ECT seems to hold promise as a variant of the conventional technique of ECT administration. It is not widely used and should be considered as experimental until additional reports of its use and efficacy are available.

DISCUSSION

Scientific Acceptability of the Literature on the Use of ECT with Schizophrenia

Contemporary standards for clinical research studies in psychiatry include rigorous diagnostic criteria, standardized treatment methods, control groups, independent or double-blind raters, specific outcome criteria, and adequate follow-up. Most of the early clinical reports in this review understandably do not meet these criteria. Riddell (72) reviewed 42 clinical research reports that had been published before 1962 and found only 10 of them scientifically acceptable. She stated, "It is apparent that not only is there a distressing lack of acceptable research into ECT as a therapeutic agent, but that very few valid conclusions can be reached from the studies which have been carried out." Riddell called for more rigorous research.

Unfortunately, many of the subsequently published research reports of ECT efficacy in schizophrenia also cannot meet current standards of acceptability, since only 18 have employed a control group for comparative purposes. Eight of these have been retrospective studies (13, 28–30, 32, 33, 49, 52, 73). Although such studies are useful in establishing trends in treatment efficacy, variable diagnostic criteria and treatment methods limit the conclusions that can be drawn.

Prospective studies that compare concurrent treatment methods are more useful in providing data about differential treatment efficacy. Twelve of the prospective studies published since 1963 have included a comparison or control group of patients. Five of these (12, 55, 58, 74, 75) studied electrode placement rather than different treatment modalities. A sixth study (11) compared ECT with fluothyl-induced convulsions. Reports of comparative studies by Childers (27) and by Murillo and Exner (63) did not include adequate diagnostic information and thus are unacceptable. Neither Gambill and Wilson (51) nor Rahman (54) included follow-up data in their reports.

Only two prospective studies that used a control population meet contemporary standards for research criteria (34, 53). Both studies used rigorous diagnostic and outcome criteria as well as a follow-up of 1 or more years.

It is discouraging to note, therefore, that with these two exceptions there have been no completely acceptable controlled prospective studies of the use of ECT for schizophrenia even though ECT has been used as a treatment for schizophrenia for over 40 years.

Treatment of the Acute Schizophrenic Patient

Despite the scientific acceptability of only a few ECT studies, the overwhelming impression to be derived from the remaining anecdotal and clinical reports is that ECT can be an effective treatment for schizophrenia. Rates of remission or marked improvement range from 40% to 80% for immediate outcome. For patients who have been ill for more than 1 year, ECT, like other treatments, is not particularly effective. However, ECT has become firmly established as a treatment for catatonic symptoms.

If lack of readmission is taken as the criterion for treatment success, then the Camarillo comparative study strongly suggests that ECT does approximately as well as neuroleptic medication 3 to 5 years after initial treatment. On this basis neuroleptic drugs are only slightly favored over ECT. On a cost-effectiveness

basis, however, ECT is clearly inferior to drugs alone or to drugs plus psychotherapy (76).

If the treatment outcomes are approximately equal several years later, then differential production of side effects must be considered in order to establish clinical prescribing preference. ECT produces memory loss, which is usually transient. Memory loss is correlated with electrode placement, as well as with the frequency and number of seizures. The treatment of schizophrenia may require more ECT than does affective illness. Regressive ECT or maintenance ECT is particularly likely to add to the overall number of sessions a schizophrenic patient receives in a lifetime. It is possible, therefore, that a young acute schizophrenic patient who had recurrent episodes of illness may require several courses of ECT during a lifetime, thus increasing the total number of seizures. The question is, therefore, Is ECT's effect on memory cumulative over a lifetime, as radiation is for carcinogenesis?

Although a comprehensive examination of this question lies outside the scope of this review, four reports have studied the effect of ECT on memory functioning in schizophrenic patients. Perlson (77) found no intellectual deterioration as measured by psychological tests in a 27-year-old acute schizophrenic patient who received 152 sessions of ECT. However, Rabin (78) administered the Rorschach to 6 chronic schizophrenic patients who received a total of 100–134 ECT sessions and found characteristic organic personality patterns in these patients. Goldman and associates (79) administered the Bender-Gestalt test and Benton Visual Retention Test to 16 chronic schizophrenic patients who received 15–219 ECT sessions during their lifetime (mean=69.5). It had been 10–15 years since the patients' last course of ECT. The test scores of this group were compared with scores from 16 chronic schizophrenic patients who had never received ECT and who were matched for age, race, and level of education with the ECT recipients. The authors admitted that matching did not extend to the degree of pretreatment psychopathology or length of hospitalization. The ECT-treated group had significantly higher errors on the two tests than did the non-ECT group, leading the authors to conclude that cognitive impairment results from the cumulative irreversible brain damage of ECT.

Templer and associates (80) attempted to replicate this study and added the Wechsler Adult Intelligence Scale to the test battery. Twenty-two chronic schizophrenic patients who received 40–263 ECTs (mean=58.5) were compared with 22 patients who received no ECT and were matched for age, sex, race, and level of education. The authors successfully replicated original findings of inferior test performance by the ECT recipients. However, when the difference in degree of pretreatment psychopathology was controlled for, the two groups' performance on the Benton test and Wechsler scale was similar. The ECT patients' inferior performance on the Bender-Gestalt test suggested, but did not conclusively prove, permanent brain damage.

These two studies do not resolve the question of cumulative, irreversible cognitive impairment resulting from ECT use. Decreased intellectual function may have antedated the ECT, arisen from non-ECT sources, or may have resulted from inadequate oxygenation during ECT administration. The results of these studies, therefore, cannot be accepted as definitive evidence that ECT causes irreversible brain damage and/or permanent memory loss. However, the lack of unequivocal evidence of no association between ECT and memory loss casts doubt on the wisdom of using ECT with young acute schizophrenic patients, who may require a total of 50 or more treatments during their lifetime.

In deciding between ECT and neuroleptic treatment for young acute schizophrenic patients, the clinician must also consider the possibility of tardive dyskinesia in recipients of ataraxic drugs. ECT does not produce tardive dyskinesia (81). If ECT may be equivalent to drugs in long-term efficacy, would not this differential side effect favor the use of ECT? This question, like that of permanent cumulative memory loss, cannot be satisfactorily answered. The need for further research in these areas is clear.

Quality of Life After Treatment with ECT

Studies of ECT efficacy in schizophrenia that have included follow-up have almost universally used hospital readmission, ability to work, or ward behavior as the outcome criteria. Even the Camarillo study considered lack of readmission or fewest days of rehospitalization as the measure of long-term therapeutic success. This review suggests that ECT has some success in keeping patients out of the hospital. Although relapse rates are high, they seem to be correlated with duration of illness.

To my knowledge, no study to date has examined the quality of the treated patient's life after ECT. Yet there are many other factors of a schizophrenic patient's life that must be considered besides hospital readmission and work. The maintenance or development of a close human relationship, which is often impaired in schizophrenia, has not been described following ECT. There are no data on the effect of ECT on low self-esteem, lack of autonomy, autism, or pathological fear and suspiciousness, all of which contribute to a schizophrenic patient's unhappiness. Thus, it is conceivable that a patient who is successfully treated with ECT (judged by the criterion of a low rehospitalization rate) may still be leading a miserable, isolated, and fearful existence. Stated differently, there are no data to suggest that ECT qualitatively alters any aspect of schizophrenia other than the acute symptoms that require hospitalization.

The lack of data indicating the superiority of ECT

over drugs in terms of quality of life, long-term side effects, length of initial hospitalization, immediate reduction of symptoms, or cost-effectiveness suggests that ECT cannot be considered superior to neuroleptic drugs. Only the comparative follow-up data from the Camarillo study suggest that ECT may be equally efficacious to drugs; further comparative follow-up data are needed.

Treatment of Chronic Schizophrenia

Questions of cumulative memory loss after ECT as well as tardive dyskinesia after long-term high doses of neuroleptics obviously apply to the chronic schizophrenic patient. This review suggests that conventional ECT as well as regressive ECT is not therapeutic for the patient who has nonaffective schizophrenic illness of more than 2 years' duration. Although ECT may sometimes produce a diminution in symptoms, this response is usually transient and relapse rates are high. It is also possible to conclude that the likelihood of any favorable response to ECT decreases as the duration of illness increases.

Nevertheless, *some* patients who are chronically ill do occasionally show therapeutic response to ECT (82, 83). The rate of "improvement" of chronic schizophrenic patients following ECT has varied from 8% (84) and 11% (85) to nearly 50% (39). Since improvement is usually not adequately defined, no conclusions can be made regarding approximate percentages of response among chronic patients. Furthermore, relapse rates are particularly high for patients with long-standing illness. It is unlikely, therefore, that an estimate of response rate in chronic schizophrenia can be higher than 5%–10%. However, even this low rate of response would mean the discharge of a substantial number of patients from chronic institutionalization.

Since any response to ECT among chronic schizophrenic patients is likely to require more treatments than are needed for the acute schizophrenic or affectively ill patient, the risk of possible cumulative memory loss is obviously increased. Considering the overall poor response to ECT, it is unclear whether this form of treatment should ever be considered for this population. Is ECT, with its poor likelihood of response and variable incidence of memory loss, preferable to long-term neuroleptic medication, with progressive risk of tardive dyskinesia? Only future longitudinal comparative studies of the two treatments in chronic schizophrenia will conclusively answer this question.

Since a long course of treatments is to be expected if a chronic schizophrenic patient is to be treated successfully, it is particularly important to obtain informed consent from both patient and family. The explanation of the procedure must stress the risks of ECT as well as the risks of not receiving ECT, such as long-term hospitalization or tardive dyskinesia as a result of pharmacotherapy (86, 87).

CONCLUSIONS

The literature reporting the therapeutic efficacy of ECT for schizophrenia is predominantly unacceptable according to contemporary research criteria. In particular, most articles vary in the degree to which they specify criteria for the diagnosis of schizophrenia, outcome, or follow-up.

ECT has been almost completely replaced by pharmacotherapy for the treatment of acute schizophrenia and the management of chronic schizophrenia. This may be due to the poor scientific quality of the ECT studies, as well as the potential toxicity of ECT, difficulty of administration compared with drugs, and, thus, declining acceptability to patients and providers. Although a few authors still strongly advocate a primary role for ECT in the treatment of schizophrenia (19, 88–90), a secondary role for ECT is proclaimed in standard psychiatric textbooks (91–96), contemporary reviews (97–99), and in the report of the APA Task Force on Electroconvulsive Therapy (100).

As ECT has been replaced by pharmacotherapy, the length of hospital stay has declined and hospitals have unlocked their doors. This is a correlational relationship and has not been proven as cause and effect.

ECT reduces acute schizophrenic symptoms and in some cases produces a complete remission. The degree of ECT's therapeutic effect is inversely related to the duration of schizophrenic symptoms. The best results are with patients who have been ill 1 year or less. ECT is not as immediately effective as pharmacotherapy for the treatment of schizophrenic patients in the middle section of the prognostic range.

ECT is universally acclaimed as an excellent treatment for acute catatonic withdrawal or excitement.

ECT has been found useful for schizophrenic patients with depressive affect and symptoms of low self-esteem, hopelessness, and suicidal thoughts.

Although opinion is divided concerning ECT for patients with acute paranoid reactions and acute schizophrenia with paranoid features, most authors have found ECT to be beneficial.

ECT offers little hope for lasting improvement in chronic schizophrenic patients. It controls behavior and temporarily reduces symptoms, but relapse rates are very high. An occasional chronic patient will respond with lasting and significant improvement.

Opinion is divided regarding the safety and efficacy of combining ECT with neuroleptic drugs. Some reports have been enthusiastically in favor of the combination. One excellent study indicated that the combination reduces both hospital stay and readmission rate. The combination may also be employed for patients who have not responded to either treatment alone. There is no contraindication to following a course of ECT with ataraxic drugs.

Regressive ECT has produced mixed results in chronic schizophrenic patients in whom it has been

predominantly tested. It should be considered an experimental procedure at this time. Multiple monitored ECT holds promise as a new technical variation for ECT administration, but it is not conclusively superior to conventional use of ECT for schizophrenia.

There are a few suggestions that schizophrenic patients who receive many (i.e., 50) sessions of ECT during a lifetime show cumulative, irreversible brain damage as measured by paper-and-pencil tests. These data must be replicated and extended by future research.

Follow-up studies of schizophrenic patients who have been successfully treated with ECT tend to suggest a high relapse rate. In the Camarillo comparative study, patients receiving ECT and neuroleptic drugs had a nearly equivalent number of hospital readmission days. No follow-up study considers the quality of life after successful ECT. It is impossible, therefore, to state whether ECT can help schizophrenic patients live more gratifying, less lonely and frightened lives, even if they are discharged from the hospital.

Given the variable quality of reports, often contradictory findings, and abundance of different and passionate opinions regarding ECT in schizophrenia, further research is indicated.

Effects of Lithium Carbonate on Memory and Other Cognitive Functions

BY LARRY R. SQUIRE, PH.D., LEWIS L. JUDD, M.D., DAVID S. JANOWSKY, M.D., AND LEIGHTON Y. HUEY, M.D.

The authors studied the effects of lithium carbonate on memory and cognitive function in 16 psychiatric patients, who received lithium for 2 weeks and placebo for 2 weeks in a double-blind cross-over design. At the end of each treatment phase, subjects were administered a battery of memory and cognitive tests. As reported previously, lithium induced slowing of performance on certain of the perceptual motor tests; however, lithium did not cause memory impairment or a change in self-assessment of memory functions.

There has been considerable interest recently in effects of lithium carbonate on personality and cognitive function that might occur in conjunction with its therapeutic effects. Despite individual reports of memory complaints during lithium therapy (1–3), few comprehensive studies have formally assessed the effects of lithium on memory or other cognitive functions. Two double-blind studies of healthy volunteers, each using one memory test, found that lithium affected the ability to recall a list of words (4, 5). Moreover, psychiatric patients taking lithium for more than 1 year learned and recalled words more poorly than did patients not taking lithium (6), and 20%–30% of patients reported some degree of memory problems after 6 months of lithium treatment (7). Other studies have found that memory was unaffected by lithium when compared with either tricyclic drugs (8) or a drug-free condition (9, 10). Even after several years of treatment, lithium reportedly did not alter memory problems, according to patients' self-reports (11).

Received July 23, 1979; revised Dec. 12, 1979; accepted Feb. 8, 1980.

Other cognitive tests have repeatedly demonstrated that lithium can impair performance (12–17). Judd and associates (16, 17) have suggested that lithium may affect those tests requiring speed, primarily causing a slowing of performance secondary to a slowing in the rate of cognitive processing.[1] To explore this issue more comprehensively we assessed the effects of lithium on psychiatric patients, by using a battery of six memory tests, a self-rating instrument for memory complaints, and a battery of seven cognitive and perceptual motor tests.

METHOD

Subjects and Protocol

Sixteen psychiatric inpatients (15 men, 1 woman) from the San Diego Veterans Administration Medical Center voluntarily participated in the study. The subjects averaged 41 years of age (range, 22–55 years), had completed an average of 13.9 years of education (range, 10–18 years), and were diagnosed with Research Diagnostic Criteria (18)—13 had a diagnosis of alcoholism, 2 were diagnosed bipolar I (bipolar with mania), and 1 was given a diagnosis of schizoaffective disorder, manic type. Of the 13 alcoholic patients, 4 were diagnosed as having secondary major depressive disorder, 4 had secondary minor depressive disorder, and 2 were diagnosed bipolar I. Patients with affective disorder usually were euthymic, although several were depressed or mildly hypomanic at the time of the study. Informed consent was obtained from all subjects.

All subjects were withdrawn from all psychotropic medications at least 7 days before the study began. A double-blind, counterbalanced cross-over design was then used in which each subject was given oral lithium carbonate two times a day for 2 weeks in an effort to achieve desired serum levels. Half of the subjects received placebo for the 2 weeks preceding active lithium treatment, and half received placebo for 2 weeks following lithium treatment. Serum lithium levels at the end of the active lithium treatment phase averaged

[1] L.L. Judd, L.Y. Huey, D.S. Janowsky: Lithium and its effects on cognitive processing, 1979 (unpublished manuscript).

0.94 mEq/liter (range, 0.5–1.2 mEq/liter) and 0.03 mEq/liter (range, 0–0.1 mEq/liter) at the end of the placebo phase. A battery of memory tests and a battery of cognitive and perceptual motor tests were administered on days 11–13 of each 2-week phase of the study. All 16 subjects were given the memory tests, and 11 were also given the cognitive and perceptual motor tests.

On 1 of the 2 days following testing, some of the subjects received a single 3-hour challenge drug infusion or ingestion (methylphenidate, N=3; physostigmine, N=5; ethanol, N=5); the results of these studies will be described elsewhere. Since these drugs were given after testing, the subjects were always free of all drugs other than lithium or placebo for at least 12 days before testing.

Memory Battery Tests

Tests 1–6 were administered in two equivalent forms 2 weeks after treatment with lithium or placebo. These tests are known to be sensitive to the amnesic effects of bilateral ECT (19 and unpublished observations).

Test 1: Recognition of 32 items. The subjects looked at 32 items (objects, faces, nonsense drawings, words) and later attempted to select each item from a set of three (19). Retention was tested immediately after learning and again 10–12 minutes later. The score was the number of items identified out of 32.

Test 2: Paired associate learning. The subjects saw 10 pairs of unrelated nouns on three successive trials (20). After each trial the subjects saw the first word and were asked to recall the second. The score was the number of words recalled out of 10.

Test 3: Recall of a paragraph. Immediately and 10–12 minutes after hearing a short story of five lines, the subjects tried to recall as much as they could (19). The score was the number of story segments recalled.

Test 4: Drawing a geometric figure from memory. The subjects copied the Rey-Osterrieth figure (21) or the equivalently difficult Taylor figure (22) and then 10–12 minutes later, without being forewarned, tried to reproduce it from memory. The score was the number of properly located line segments based on a maximum score of 36 points.

Test 5: Remote memory for public events. This test consisted of 23 questions about persons or events in the news from 1950 to 1976. There were 6 questions about the 1950s, 9 about the 1960s, and 8 about the 1970s. The subjects were asked a specific question about each event and then to recall as much as they could about it (20). The score was the total number of facts recalled from each decade per event.

Test 6: Detection task. Of the 16 subjects, 13 took this test, which has been described in detail previously (23). The subjects read a list of 6–17 words, 2 of which 1) were the same, 2) rhymed, or 3) came from the same semantic category. In each list 0, 3, or 6 filler words intervened between the 2 critical words. The subjects knew which type of detection they were to make (repetition, rhyme, or category) and were asked to signal when they detected the second critical word. The score was the percentage of correct detections.

Test 7: Self-rating scale for memory complaints. The subjects filled out an 18-item questionnaire that was sensitive to the memory complaints associated with ECT (24) to assess aspects of their memory abilities "now compared to before I began to feel bad and came to the hospital." Ratings were made on a scale from −4 (worse than ever before) to +4 (better than ever before). A list of all test items has appeared elsewhere (24).

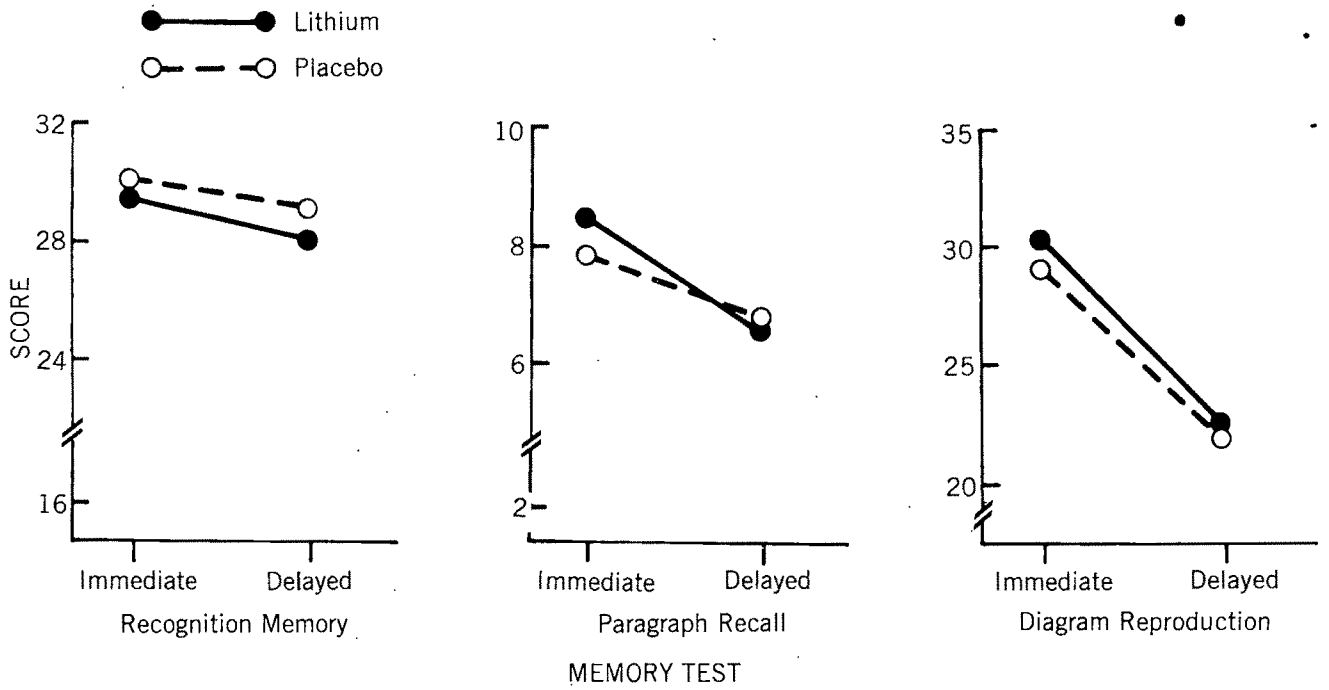
Cognitive and Perceptual Motor Battery Tests

All tests were administered in two equivalent forms 2 weeks after treatment with lithium or placebo. Additional information and original sources for all tests have been presented elsewhere (16, 25).

Test 1: Porteus maze. The subjects were presented a labyrinth maze printed on paper and instructed to start in the center and trace a path to the outside edge without crossing any lines or lifting the pencil from the page. The score was the time required for completion, the number of wrong turns, and the number of times that lines were crossed.

Test 2: Serial sevens. The subjects were instructed to count backwards by sevens from a given number between 500 and 506. The score was the number of correct responses and the percent of errors in a 2-minute period.

Test 3: Number learning task. The subjects were given seven trials to learn correctly a 14-digit number, and seven more trials to learn a second number. The score for each learning test was the total number of digits correctly recalled in seven trials.



Test 4: Speed of closure. The subjects were instructed to scan 22 rows of 46 letters for 2 minutes and then to circle any 4-letter word. The score was the number of letters scanned, the number of correct words identified per 100 letters scanned, the percent of correct words not identified (omission errors), and the percent of "words" incorrectly identified (commission errors).

Test 5: Minnesota clerical. The subjects scanned a list of number pairs for 8 minutes. Some of the pairs were identical and others were not, and the subjects were asked to check the identical pairs. The score was the number of pairs scanned, the percent of identical pairs not checked (omission errors), and the percent of nonidentical pairs checked (commission errors).

Test 6: Digit symbol substitution. This paper-and-pencil timed test, selected from the Wechsler Adult Intelligence Scale, required subjects to convert a sequence of symbols into a sequence of digits according to a code printed at the top of the page. The score was based on the number of correct responses in 90 seconds.

Test 7: Trail-making A and B. These were two pa-

FIGURE 1
Effects of Lithium and Placebo on Recognition Memory (Test 1), Paragraph Recall (Test 3), and Diagram Reproduction (Test 4) Memory Tests for 16 Psychiatric Inpatients

per-and-pencil timed tests from the Halstead-Reitan Battery, in which subjects connected as quickly as possible a sequence of numbers, or numbers and letters, arranged out of order on a page. The score was the amount of time required for completion.

RESULTS

The data for each test were submitted to an analysis of variance with one repeated factor (drug condition: lithium or placebo) and one independent factor (drug order: lithium-placebo or placebo-lithium). There were no significant effects of lithium on any of the memory tests (see figure 1 for the results of tests 1, 3, and 4). In addition, for paired associate learning (test 2), scores improved from an average of 4.6 correct on the first trial to 8.6 correct on the third trial, and there was no effect of drug on learning ($F=2.4$, $p>.10$). On test 5 (remote memory) subjects recalled an average of 2.0 facts about each event from the period 1950 to 1976, and there was also no effect of drug condition on recall ($F=1.0$, $p>.10$). On test 6 (short-term detection), subjects were best at detecting repetitions of words (91% correct), worst at detecting rhymes (63%), and intermediate at detecting words belonging to the same semantic category (73% correct). In addition, performance declined from 96% correct, when the two words to be detected were read in immediate succession, to 57% correct when six words intervened between the critical words. Performance on this task was almost identical under lithium and placebo conditions, and the average difference in performance across the 9 experimental conditions (3 types of detection×3 delays) was 3.6%. Order effects emerged for three of the six tests (tests 2, 3, and 6); i.e., subjects receiving lithium-placebo performed differently than those receiving placebo-lithium. On two occasions the lithium-placebo order yielded better performance (tests 2 and 3), and on one occasion the placebo-lithium test yielded better performance (test 6).

Self-ratings for memory functions during the lithium and placebo phases of the study (test 7) showed that the subjects responded somewhat differently to the various test items ($p<.05$), but on each of 18 items they rated their memories virtually the same when they were taking lithium as when they were taking placebo ($F<1.0$, $p>.10$).

Whereas lithium did not impair memory test scores for all 16 subjects together, it seemed possible that there might be a measurable relationship between serum levels of lithium and memory test scores. Accordingly, we computed correlations between serum levels and scores on each memory test. These correlations were significant for tests 1 and 4 ($r=-.61$, $p<.02$), indicating that subjects having higher lithium levels performed more poorly than subjects having lower lithium levels. For test 6, which measured detection in short-term memory, the correlation was positive ($r=.54$, $p<.05$), indicating that higher lithium levels were related to better performance. We also computed a composite memory score for tests 1–5 by ranking performance on each test and then summing the ranks for each subject across the five tests: a low composite

TABLE 1
Mean Cognitive and Perceptual Motor Test Scores of 11 Psychiatric Inpatients Receiving Lithium or Placebo

Test	Mean Score	
	Placebo	Lithium
1 (porteus maze)		
Time (seconds)	68.2	106.4
Cognitive errors	1.0	1.7
Motor errors	3.3	2.3
2 (serial sevens)		
Number completed	32.1	29.0[a]
Errors (%)	9.6	8.9
3 (number learning task)		
1st test	45.9	57.8
2nd test	51.0	43.9
4 (speed of closure)		
Number of letters scanned	334.6	320.6
Number of words correct per 100 scanned	5.2	5.1
Omission errors (%)	19.9	24.8[a]
Commission errors (%)	4.5	0.0[b]
5 (Minnesota clerical)		
Number completed	131.6	116.6[b]
Omission errors (%)	1.5	1.5
Commission errors (%)	2.4	2.1

memory score indicated good performance and a high score indicated poor performance. The correlation between lithium serum levels and the composite memory score was significant (r=.66, p<.01), indicating that higher serum levels were associated with poorer performance.

The results for the cognitive and perceptual motor battery are shown in table 1. Some drug order and practice effects appeared, but these factors were not significant on tests in which significant effects of drug treatment were found. The subjects performed somewhat worse during the lithium phase than during the placebo phase on nearly every test in the battery. On test 4 the subjects performed significantly better during lithium than during placebo as measured by one of the error scores (commission, p<.05). For two of the seven tests (tests 5 and 6) the subjects performed significantly worse during lithium than during placebo; the subjects taking lithium completed fewer items on the Minnesota clerical test (p<.05) and copied fewer symbols in the Digit symbol substitution test (p<.01) than when they were taking placebo. Since accuracy was not affected by lithium on any test, the effect of lithium appeared to reflect a slowing of performance rate.

We next computed correlations between serum levels of lithium and scores on each performance test. The relationship between serum levels and performance on test 7 (Trails B) was significant (r=.75, p<.01). We also computed a composite performance score for each subject by ranking performance on each test and then summing the ranks for each subject across the seven tests. There was no measurable relationship between lithium serum levels and the composite performance score (r=.19, p>.3).

Mood ratings as assessed by the Profile of Mood States (26) were available for 13 of the 16 subjects who took the memory tests and 9 of the 11 subjects who took the cognitive and perceptual motor battery. The POMS was administered on days 13 or 14 of each 2-week phase of the study. Correlations were computed between each of the eight scales of the POMS and the composite memory test score or performance score. None of these correlations was significant (p>.2).

DISCUSSION

Taken together, the results indicate that nearly 2 weeks of lithium treatment at an average dose of 0.94 mEq/liter did not significantly affect performance on formal tests of learning and memory. The results obtained with a newly developed self-rating instrument also indicated that lithium did not cause subjects to experience their memory as impaired. Nevertheless, the doses we studied exerted measurable effects on the central nervous system on certain tests requiring speed; this is consistent with results previously reported for such tests (12, 14–17). Thus, lithium appeared to cause slowing of performance in the absence of impairment of learning and memory. Since memory defects are commonly an early sign of diffuse cortical dysfunction in neurological disease, the finding that memory was not measurably affected by lithium suggests that in the doses we used lithium's effects on higher cognitive function are on the average rather unremarkable.

It is possible, of course, that measurable effects of lithium on memory would have appeared if treatment had been continued longer than 2 weeks. In one study (7), some memory complaints developed after 6 months to 2 years, in 20%–30% of subjects on maintenance lithium therapy. In another study (6), patients taking lithium for 1–4 years scored more poorly on a memory test than a group of patients not taking lithium; however, as these authors noted, it is possible that the findings reflected differences in group composition; a within-subjects experimental design is needed to settle this issue unambiguously. It also seems possible that effects on memory would have emerged in our study if lithium had been administered in higher doses, and our finding of a negative correlation between serum levels of lithium and memory test scores is consistent with this suggestion. Thus, the higher doses of lithium that we used may have tended to impair performance, although on the average the doses we used caused no measurable effect. The doses we used (0.5–1.2 mEq/liter) are those typically used for

maintenance lithium therapy but do not extend across the full range of doses that might be used in acute lithium treatment (up to 1.5 mEq/liter). Judd's informal clinical observations have also suggested that memory complaints are more frequent at higher doses of lithium (serum levels above 1.2 mEq/liter).

It is also important to note that our findings are based on a heterogeneous group of psychiatric patients and not on a group of patients with affective disorder selected because of their suitability for lithium therapy or on a group of healthy, nonhospitalized volunteers. In two previous studies of healthy volunteers (4, 5), 1–2 weeks of lithium treatment affected performance on a memory test that assessed recall of a word list after a delay. However, one of these studies (5) involved only 6 subjects, and it was not noted whether the difference between lithium and placebo was statistically significant. The other study (4) involved 12 subjects, and lithium's effect was to impair recall of words learned 2 weeks previously; lithium did not affect initial learning or recall after a 2-hour delay.

In summary, in this study we used six formal memory tests proven sensitive to the amnesic effects of ECT (19, 27), and lithium had no overall effect on memory; on a seventh testing instrument sensitive to the memory complaints associated with ECT (24), lithium did not cause a subjective sense of memory impairment. It therefore seems reasonable to suppose that lithium's effect on memory, at doses of 0.5–1.2 mEq/liter, is rather unremarkable. Since memory test performance tended to correlate inversely with serum lithium levels, higher doses of lithium (i.e., above 1.2 mEq/liter) might have produced greater effects on memory than we observed. Although further work is needed to evaluate fully the effects of lithium on cognitive function, our results, together with previous results obtained under the same experimental conditions (16–17), are consistent with the view that lithium affects the rate of performance on cognitive and perceptual motor tasks.

Couples' Reactions to Male Infertility and Donor Insemination

BY DAVID M. BERGER, M.D.

The author interviewed 16 couples after the husband had been diagnosed as infertile. Eleven husbands experienced a period of impotency. Fourteen of the women experienced anger toward the husband, psychiatric symptoms, and/or dreams about their concern for the husband, a wish to be rid of him, and guilt over this wish. Ten couples had decided to pursue donor insemination; 6 had delayed 1¾ to 4 years after the diagnosis of infertility and had a better adjustment than 3 of the 4 couples who did not. The author believes that the total secrecy involved in donor insemination inhibits the working through of conflicts about infertility and donor insemination itself.

In order to study conflicts and behavior patterns in couples in whom the male partners had been discovered to be infertile, I interviewed 16 married couples after the diagnosis of azoospermia or severe oligospermia had been made in the reproductive biology clinic of a 600-bed urban general hospital. Excluded were couples who had been aware of the husband's infertility before marriage, couples in whom the woman had been found to have physical pathology that could have contributed to the infertility, and couples in whom one of the partners had severe psychopathology (e.g., schizophrenia or manic-depressive illness). The women's ages ranged from 21 to 34 years. The men's ages ranged from 21 to 38 years. At the time of the interview 10 of the couples had already decided to undertake donor insemination, 2 couples had decided against it, and 4 couples were undecided. Because the clinic is a special unit that receives referrals from other physicians, for only 2 couples was the diagnosis of male infertility a novel finding. The couples had known about the infertility for 8 months to 4 years before the interview.

The interview focused on a number of questions: What was each partner's reaction to the diagnosis of the husband's infertility? Could changes in feeling, thinking, or behavior be detected in the individual partners or in the relationship? What conflicts could be inferred from these changes? Was there any pattern to the couple's choosing donor insemination, and how did they feel about keeping it secret? The partners were encouraged to talk freely about whatever they felt to be important. I interposed questions to fit the subject at hand and requested dream reports of every individual.

FINDINGS

The Men

Only 3 of the 16 men were symptom free. Ten reported a period of impotence that had lasted 1 to 3 months (mean=1¼ months) after the discovery that they were azoospermic or oligospermic. Before this discovery, the frequency of their sexual activity had been 1 to 3 times per week. The onset was within 1 week of being informed of the diagnosis. Another subject was impotent for at least 4 months (the impotence had not improved at the time of the interview). This subject felt that the impotence was precipitated by "an attack of kidney stones" 3 years after the discovery of oligospermia. Three of the 11 men with impotence also admitted to depression, 1 had an exacerbation of peptic ulcer symptoms, 1 man began an affair (which he felt cured his impotence) within a month of discovering he was azoospermic, and 1 man suffered whiplash in a car accident 1 month after he was informed of his azoospermia and was incapacitated for 6 months. Two of the 16 men reported no change in sexual pattern or mood, but the level of their sexual activity was low to begin with (frequency of intercourse was less than once per month), and only 3 men, whose sexual activity level had been satisfactory, reported no change in sexual pattern or mood. These findings are striking when compared to the incidence of cessation of marital intercourse in a general population (1).

Only in the couple in whom the man had embarked on an affair shortly after the diagnosis was made did the couple report a marked change in attitude toward the wife. Some of the wives mentioned that their husbands appeared more withdrawn than in the past.

In addition to dreams that occurred after the discovery of infertility, I requested specifically dreams from

the night before the interview, on the premise that anticipation of the interview might stir up conflicts related to the infertility. Only 5 of the 16 men were able to report dreams. All were from the night before the interview. The only unvarying finding was that heterosexual encounters were absent in all 5 dreams. This is in accord with the reported withdrawnness of the men after the discovery of infertility.

The Women

None of the 16 women reported a decrease in their frequency of sexual activity, and 3 reported an increase within 2 months of discovering their husband's infertility. Six of the 16 couples reported that the wives were significantly angrier toward the husbands shortly after the diagnosis was made. In 1 couple this led to a temporary separation. In 2 other couples this changed attitude led to the wife's having an affair in which no contraceptives were used. The other 3 couples stated that their marriage had been "on the rocks" for several months. Despite the fact that the marital difficulties occurred within 3 months of the husband's diagnosis, not one of the couples had linked the difficulties with the infertility.

One woman developed a fear that she would give birth to a defective child. The phobia was accompanied by rage and envy directed at others "who did have children but were terrible parents."

The dreams these women reported were remarkably consistent. One of the 16 women volunteered that within a week of first learning of her husband's infertility she had a dream in which she attempted to protect her husband from attack by criminals. Eight other women reported that the night before the interview they had had dreams in which the husband fell ill, committed suicide, or was physically or verbally assaulted. In only 1 of these 9 reports was the wife the aggressor; in the others her role was protector and comforter.

Another woman reported the following dream: "I was pregnant and very happy about it. Then I discovered that I had gained too much weight and would die." In the interview this woman stated that if the couple's infertility were to become known to others she would prefer people to believe that it was her problem, not her husband's. Moreover, since the discovery of the infertility she had become increasingly preoccupied with her husband's weight; her husband was obese and she worried that his health was declining.

Ten of the 16 women reported dreams with a similar content. None of them had experienced such dreams in the past. Three themes appeared to be incorporated in these dreams: 1) the woman felt bad (perhaps guilty) about the husband's infertility, 2) she wished to be rid of her husband, and 3) she felt guilty about her wish to get rid of him. Two women reported dreams in which these themes were not evident, and 4 women could not recall any dreams. The dream reports were compared to those of a control group of 10 women (ages 20 to 31 years) whose infertility workup revealed no evidence of physical pathology in either spouse: only 1 dream contained aggression directed at the husband. Compared to studies of dream reports gathered from the general population (2, 3), the dream reports of the women in this study contain a higher incidence of violence and a much higher incidence of violence directed at the spouse. The finding that more women than men report dreams is consistent with the findings of surveys of the general population.

In summary, after the revelation that their husbands were infertile 4 women developed symptoms (phobia, rage at the husband that led to marital difficulties) but no significant dream findings, 2 women had symptoms as well as significant dream findings, 8 women had significant dream findings but no symptoms, and 2 women had no symptoms and no significant dream findings.

The Decision to Pursue Donor Insemination

At the time of the interview 10 of the 16 couples had decided to undertake donor insemination, 2 had decided against it for religious reasons, and 4 were undecided or preoccupied with marital difficulties.

Six of the 10 couples who had decided in favor of pursuing donor insemination had delayed before arriving at their decision; they stated that they had been undecided for several months after donor insemination was first discussed with them. For these 6 couples the time between the discovery of the infertility and the interview ranged from 1¾ years to 4 years (mean=2¼ years). Two couples denied any conscious intent to delay their decision as long as they had (3 years) but for some time had been considered "problem patients" at the clinic because they were difficult to contact and would cancel appointments. Two couples felt that job difficulties contributed to the delay. Only 2 couples attributed the delay entirely to indecision and the husband's requiring time "to get over feeling bad." These 6 couples decided on donor insemination without further requests for psychiatric intervention. This pattern of delay is suggested in the report of Nijs and Rouffa (4) and supports Beck's contention (5) that deliberation (although it may be unconscious) precedes the decision to undertake donor insemination.

Four of the 10 couples who had decided to pursue donor insemination reported that they had been relatively certain about their decision from the start (although this certainty was voiced primarily by the wife). The time between their discovery of the husband's infertility and the interview was 18 months or less. To a large extent this time lapse could be accounted for by waiting periods entailed in referral to the clinic, consultations, and completion of the workup for both partners. How these 4 couples fared is revealing. One couple decided to adopt a child after an incomplete course of donor insemination. Another couple became disenchanted with our clinic, although before their departure the husband came to see me be-

cause he and his wife were finding intercourse painful. The third couple, in which the wife had developed a phobia as well as diffuse rage, was the only couple in this group to receive the recommendation that individual psychotherapy for the wife was necessary before proceeding with donor insemination. The fourth couple had known that the husband had had surgery as a child for an undescended testicle and that it had been crushed in the process, so that the man's infertility did not come as a surprise.

These findings suggest that a period of delay before deciding to pursue donor insemination is associated with a better adjustment to it. That another couple, who chose not to pursue donor insemination, had transferred to our clinic because they felt "rushed into donor insemination" by their previous physician supports this observation.

How did the couples feel about the concealment that accompanied donor insemination? Nine of the 10 couples who had chosen to pursue donor insemination felt that the secrecy presented no problem. One couple felt that it would be burdensome, that it would isolate them from others. This couple discontinued treatment shortly after its initiation and decided to adopt a child. When asked what benefits might derive from the secrecy, most couples responded with vague statements: "It's no one's business," "No one has to know." On further questioning 7 of the 10 couples stated that the secrecy would somehow benefit the child ("We don't want the child to feel different").

Three couples stated that "their" infertility would be kept from others. Repeated questioning was required before any of the 10 couples would admit that it was the husband's infertility that the secrecy might serve to hide. The tendency was to cling to phrases such as "our infertility." Interestingly, this specific admission was usually voiced by the women. It was also the women who seemed to react most critically to the possibility of sharing the secret with others as well as with the child who would result from donor insemination. These findings are impressionistic and do not lend themselves to clear-cut conclusions. However, they are consistent with the findings of Farris and Garrison (6) that, in frequency of response to the question of why couples chose donor insemination over adoption, keeping the husband's infertility hidden did not rank very highly. One might infer from these findings that the partners had resolved their conflictual feelings about the man's infertility. However, the apparent reluctance to admit that one obvious purpose of the secrecy was to conceal the male partner's infertility, coupled with evidence from the women's dream reports, suggests that there still remained unresolved feelings and that the concealment of donor insemination permitted displacement to take place, in most cases a shift in concern toward the child who would result from donor insemination.

DISCUSSION

The findings describe a specific common conflict pattern in couples after the diagnosis of male infertility: impotence, depressive mood and/or depressive equivalents in the husband, and hostility and guilt in the wife. In only 2 of the 16 couples did neither partner reveal signs or symptoms that would provide evidence for this pattern. The pattern is consistent with the findings of Gerstel (7) and Watters and Sousa-Poza (8) and suggests that the impotence deserves to be viewed as an interactional problem and not solely the man's problem.

The finding that a period of delay is associated with a better adjustment than is a rush to pursue donor insemination supports the views of Gerstel (7) and Watters and Sousa-Poza (8) that inability to mourn the infertility before turning to donor insemination contributed to their clients' later difficulties. The findings suggest that the decision to pursue donor insemination involves two problem-solving stages: 1) coming to terms with the husband's infertility, and 2) confronting the problems of donor insemination itself, and that the total secrecy that surrounds donor insemination may interfere with the successful progression through this two-stage process and may contribute to a blurring of the two separate tasks. Difficulties ensue, not because there is conflict (as Gerstel [7] and Watters and Sousa-Poza [8] suggest), but because the conflict has not been worked through and resolved. The implication for clinical management is that serious discussion relating to donor insemination might best be postponed for 3 to 4 months after completion of the infertility workup.

This study offers tentative support for the hypothesis that the anticipation of some openness, at least between parents and the future child, as opposed to total secrecy, might prove psychologically beneficial. Certainly this issue cannot be overlooked by physicians and deserves further study.

The *DSM-III* Personality Disorders Section: A Commentary

BY ALLEN FRANCES, M.D.

The author reviews the DSM-III *section on personality disorders, discusses several of its more controversial diagnoses, and suggests some possible alternatives. He attributes the continued low reliability of personality diagnoses, compared with the other major sections of* DSM-III, *to two inherent obstacles: the lack of clear boundaries demarcating the personality disorders from normality and from one another, and the confounding influence of state and role factors. Nonetheless, the* DSM-III *multiaxial system highlights the importance of personality diagnosis and, together with the provision of clearly specified diagnostic criteria, achieves a considerably improved reliability compared with previous nomenclatures.*

The multiaxial diagnostic system introduced by *DSM-III* serves to highlight the importance of the personality disorders and to recognize their frequent coexistence with, and possible contribution to, the other psychiatric disorders. *DSM-III* provides separate axes—Axis I for all other clinical syndromes and Axis II for personality disorders—to ensure that the personality disorders not be overlooked "when attention is directed to the usually more florid Axis I disorder" (1). This concern arises from accumulating evidence that the quality and quantity of preexisting personality disturbance may indeed influence the predisposition, manifestation, course, and response to treatment of various Axis I conditions (2–7). The separation of Axes I and II has contributed to the increased diagnostic reliability achieved by the whole system. Evaluators are now encouraged to label both the clinical syndrome and the personality disorder (when both are present), rather than being forced to arbitrarily and unreliably make a choice between them.

This paper discusses some of the obstacles to the establishment of a reliable nomenclature of personality diagnosis. It also provides a critical review of the *DSM-III* section on personality disorders, particularly several of its more controversial diagnoses. As a member of the Advisory Committee on Personality Disorders to the APA Task Force on Nomenclature and Statistics, I acknowledge considerable bias in my presentation. Undoubtedly, I have blind spots that favor some of the choices made in *DSM-III* and may also be taking this last opportunity to argue against choices that I disliked. No one who worked on *DSM-III* had the quixotic goal of achieving any lasting or perfect solutions. It is my hope that a continued discussion of the controversies and decisions that resulted in *DSM-III* will encourage the research and debate required for an improved *DSM-IV*.

LIMITATIONS TO RELIABILITY

Previous clinical systems of personality diagnosis were plagued by very low reliability (8). Although *DSM-III* has improved on this considerably, the personality disorders as a group still attain the lowest reliability of any major category in the classification (9). There are at least two inherent reasons for this: 1) most of the personality disorders are probably no more than the severe variants of normally occurring personality traits that are distributed continuously and without clear boundaries to indicate pathology, and 2) personality assessment is inevitably confounded by intercurrent state and role factors. I will discuss these obstacles in turn.

In order to classify disorders into separate types, one ideally requires that they be distinct and mutually exclusive and that the number of cases falling at the boundary between disorders be relatively few (10). Although the organic, schizophrenic, and affective disorders all retain their fair share of fuzziness, these categories are to some extent discontinuous from one another and discrete from normality. In comparison, the various personality disorders are not at all clearly distinct from normal functioning or from each other (or even, as is discussed below, from Axis I conditions). *DSM-III* states, "It is only when personality traits are inflexible and maladaptive and cause either significant impairment in social or occupational functioning or subjective distress that they constitute personality disorders." Although in most instances *DSM-III* attempts to carefully and operationally define its criteria, it provides no definitions or quantifications for the

terms "inflexible," "maladaptive," or "significant." It would indeed be difficult to make these concepts operational. Since each clinician is left to his or her own judgment in deciding whether a particular degree of personality impairment should be regarded as disorder or merely a normal trait, this decision is made with only fair reliability.

In addition, the various personality disorders are, to some extent, correlated and continuous with each other (11). Some of the diagnostic criteria appear, in more or less similar language, under more than one category. *DSM-III* does attempt to soften the potential rigidity and inapplicability of the category system to personality diagnosis by allowing for multiple and mixed diagnoses. Although this undoubtedly constitutes the only possible current compromise, there is another method of personality diagnosis that may receive increasing attention in the future. The alternative to the *DSM-III* categorical classification would be the use of a dimensional system. This method has been extensively studied by psychologists. Among the best-known factor scales are those of Eysenck (12), Cattell (13), Leary (14), and McLemore and Benjamin (15); the MMPI is a widely used nonfactorial scale.

A dimensional system avoids many problems of the categorical approach. It is, at least theoretically, the more applicable method for describing normally distributed traits that can be quantified and measured. As this applies to *DSM-III*, the patient might be rated (perhaps on a scale of 1 to 10) for each personality characteristic rather than being diagnosed within one or another distinct personality type. This procedure might greatly improve the description of patients who are on the boundary between normality and disorder or between one and another personality disorder. The dimensional system successfully renders continuities and saves information that is lost in the forced choice of just one or the other category. It also lessens the reification of categories and the accompanying halo effect on clinicians, who may perceive patients as neatly fitting into one or another category while perhaps ignoring those traits outside the anticipated cluster.

There are substantial reasons why *DSM-III* continues to apply the more traditional categorical approach in the face of these undeniable advantages to personality diagnosis of a dimensional system. Kendell (10) has observed that clinicians naturally think in terms of categories even if research scientists tend to prefer dimensions. Dimensions may provide more information than can be conveniently used and often seem too complicated for routine clinical discourse. The creation of categories serves to reduce information overload, abstract what is most crucial, and convey a more vivid, if less accurate, picture of the patient. It is good to realize that the evolution of diagnostic nosologies must be one of the most conservative of clinical endeavors; radical departures tend to be ignored. It would certainly be premature to demand widespread conversion to a dimensional system at this time. However, it is possible that with the future widespread availability of computers, psychiatry will prefer a dimensional system, at least for personality diagnosis.

The second inherent limitation to the reliability of the diagnosis of personality disorders results from the difficulty in distinguishing and untangling trait from state and role factors. The *DSM-III* definition of personality disorder does address and, in theory, solves these problems. Personality traits are defined as enduring patterns exhibited in a wide range of activities, recognizable by adolescence or earlier, and continuing throughout adult life. In actual practice, however, it is often quite impossible on cross-sectional evaluation to decide to what extent the current behavior and clinical picture represent an enduring and lifelong pattern or to what extent they are being strongly influenced by the patient's current state and/or role expectations. The interaction of trait and state is inherently confounding and difficult to analyze. It may be impossible to eliminate completely the possible influence of Axis I conditions in the assessment of personality disorders. Many studies have ignored the fact that the patient's current mood inevitably tends to contaminate the evaluation of his or her long-standing traits. The Eysenck neuroticism scale, supposedly a personality measure, has been found to be very sensitive to mood changes and may be more a measure of depression than of personality impairment (16). Only repeated evaluations and careful history taking (perhaps also using relatives) can minimize the contamination of current state factors. The multiaxial system is a useful advance in its recognition of the possible mutual influence of personality and Axis I disorders and its provision of independent ratings for each.

The trait-role overlap is almost as difficult to disentangle. Within an overall personality pattern, each individual is certainly capable of a range of behaviors that are differentially selected depending on the contingencies, expectations, or role assignments of the particular current social environment. Personality disorder is by definition a pervasive and inflexible set of maladaptive behaviors that occur widely and not exclusively in response to a specific set of circumstances. A pathological reaction that is elicited by only one particular and unusual stimulus (e.g., an Army recruit's disobedience in boot camp) would be defined as an adjustment, not a personality, disorder. In order to qualify for the often carelessly applied diagnosis of passive-aggressive personality disorder, the behavior in question would have to be general, long-standing, maladaptive, and not merely an isolated role response to one difficult situation. In any given evaluation of personality, the consultant must judge whether the patient's behavior is deeply ingrained or whether it is merely a particular reaction to the current environment, including, incidentally, the often unfamiliar and stressful environment of the psychiatric evaluation.

A CRITICAL REVIEW

The following remarks constitute a critical review of the *DSM-III* section on personality disorders. The criticisms must be understood in the general context of my overall enthusiastic approval of this section. For several years I have had opportunities to use it for clinical, teaching, and research purposes and have found it to be clinically and heuristically helpful and a vast improvement over *DSM-II*. The following discussion assumes and probably requires some familiarity with the *DSM-III* section on personality disorders, which might profitably be read simultaneously.

Additions and Deletions

Four of the *DSM-II* personality disorders have either been eliminated from the *DSM-III* classification or transferred to other of its sections. The diagnosis of asthenic personality had been rarely used anyway and was probably indistinguishable from chronic mild depression. The diagnosis of inadequate personality dealt with the patient's functional level rather than describing a distinct behavior pattern. These two diagnoses were retired, probably without mourners. The diagnosis of explosive disorder was transferred out of the personality disorders section because its *DSM-III* definition requires an intermittent rather than a continuous course. There was some support for including a diagnosis of impulsive personality for patients whose outbursts are consistent with deeply ingrained overall personality functioning. As a compromise, impulsive personality has been listed as one of the possible other personality disorders but without specific criteria. The transfer of cyclothymic disorder to the affective section will be discussed in more detail below. The rationale for most of the five new categories of personality disorders—the schizotypal, borderline, narcissistic, avoidant, and dependent—will also be discussed.

Clusters

There is a comment in the introduction to the section that the personality disorders are grouped into 3 clusters: 1) the paranoid, schizoid, and schizotypal disorders are characterized by odd or eccentric behavior; 2) the histrionic, narcissistic, antisocial, and borderline disorders are characterized by dramatic, emotional, or erratic behavior; and 3) the avoidant, dependent, compulsive, or passive-aggressive disorders are characterized by anxious or fearful behavior. The reader should understand that this clustering does not arise from any particular evidence. In fact, most of the criteria clusters that define the 11 defined personality disorders are based only on clinical intuition and impression that has yet to be confirmed by factor analysis or other forms of validation (i.e., follow-up, family, psychological test, or response to treatment studies). Allport and Odbert (17) gathered 4,500 personality adjectives that were listed in the dictionary. There is no particular reason to believe that the 11 personality types described in *DSM-III* are the most appropriate number or grouping of personality traits or that the criteria best cluster as they now stand. On a more optimistic note, there is some evidence that the factor analyses of items derived from self-report questionnaires turn up approximately the same syndromes as had been derived intuitively by clinicians (18, 19).

Handling of Spectrum Disorders

There is some inconsistency and an overcompensation for past historical errors in the classification of the schizophrenic and affective spectrum disorders. In order to keep psychotic conditions together and to narrow the diagnosis of schizophrenia, which has been applied overinclusively in the United States (20), *DSM-III* places the presumed nonpsychotic spectrum disorder (schizotypal personality) within the personality disorders section. This is in itself a useful advance, but, simultaneous to the taming of schizophrenia, *DSM-III* may have become paradoxically overinclusive with the affective disorders. The presumed affective spectrum disorders—cyclothymic and dysthymic—do not join the schizophrenia spectrum disorder in the personality section but instead are listed with the major affective disorders. This placement of cyclothymic disorder is agreeable enough because there is fairly compelling evidence of its close relationship to the major affective disorders (21). The inclusion of dysthymic disorder (chronic depressive disorder or depressive neurosis) is a much more controversial and worrisome decision. Dysthymic disorder probably includes an extremely heterogeneous group of patients. They may have vegetative symptoms indicative of an affective disorder; psychological conflicts that make them pessimistic, self-defeating, and unhappy; a chronically difficult life situation; or various mixtures of the above.

DSM-III would have been more consistent had it selected one way to handle both the schizophrenic and the affective spectrum disorders. If dysthymic disorder must be included in the affective section, it should have required as an essential criterion the presence of vegetative symptoms; this is not the case now. Nonvegetative chronic depression should have appeared separately under one or another title (I would have preferred depressive or masochistic personality) in the personality disorders section.

New Categories of Schizotypal and Borderline Personality Disorders

The introduction of two new categories, the schizotypal and borderline personality disorders, represents a major clarification of what has been a very confusing classification. The separation of these two different, but at times overlapping, types of "borderline" disorders should improve the level of clinical discourse and research. The manner in which the criteria

were derived and tested has been well described (11) and need not be reviewed here.

Perpetuation of the Term "Borderline Personality Disorder"

The perpetuation of this term caused considerable controversy and resulted only from the lack of wide acceptance of any substitute term. Many feel that the concept of borderline has been so variously and loosely applied that it has lost all precise meaning and shape. It is no longer clear what it "borders" on, especially since the border to schizophrenia is now occupied by the schizotypal personality disorder and the border to affective illness by the cyclothymic and dysthmic disorders. There are, in fact, three additional ways that the term "borderline personality" has been used: 1) descriptively, to define by symptomatic similarities a particular syndrome of unstable personality (this is the sense of the *DSM-III* usage), 2) psychodynamically, to define an inferred level of personality organization somewhere between the psychotic and neurotic levels of integration and with characteristic deficits in psychic structure (which may coexist with any of the descriptive personality types), and 3) as a rating of severity of impairment indicating the presence of any marked character disorder (regardless of its particular descriptive or structural characteristics).

It is yet to be determined to what extent these three uses correlate with one another in the groups they define. Since the diagnosis borderline personality has attained such an unusual popularity, it is probably helpful to have a definite set of criteria on which to base a more precise discussion and research investigation. The major dispute regarding the criteria that were chosen concerned the advisability of an additional essential feature—that the patient must have displayed transient, self-limited deficits in reality testing. This suggestion would have considerably narrowed the borderline personality group and rendered it more homogeneous. It was voted down pending the accumulation of data on the relationship between transient psychotic episodes and the rest of the syndrome of instability.

Antisocial Personality Disorder

Surprisingly, this was the most controversial of all the personality disorders. The *DSM-III* diagnostic criteria specifying antisocial personality are indeed clear and reliable and have been the most carefully studied (22), but they may have missed the most important clinical point. Using criteria comparable to those in *DSM-III*, approximately 80% of all criminals are diagnosed as antisocial (23). Many investigators have suggested the inclusion of additional items that might indicate the individual's capacity for loyalty to others, guilt, anticipatory anxiety, and learning from past experiences. Some distinction between antisocial and dyssocial patterns of behavior was included in both *DSM-I* and *DSM-II* and is reflected in the current definition of childhood conduct disorders in *DSM-III* (24). These are divided into the socialized and undersocialized subtypes—a separation that seems to have some usefulness in predicting adult behavior. It has also been shown that if criminals are evaluated with more traditional and less inclusive criteria, only 30% are diagnosed as having antisocial personalities (25). For clinicians who work in prisons, it would seem to be more useful to have criteria that distinguish those criminals who are capable of loyalty, anxiety, and guilt from those who are not, since the behavior and management of each group are likely to be quite different. There was also considerable concern that the *DSM-III* criteria would be too easily and universally attained by individuals growing up in rough and deprived areas.

Schizoid and Avoidant Personality Disorders

The distinction between these two disorders is a new one. Individuals with these disorders might closely resemble each other, although the individual with an avoidant personality is much more likely to have achieved at least one close relationship. By definition, the major difference between the categories resides in the patient's motivation for relative social isolation. The patient with an avoidant personality craves closeness but avoids it because of fears of criticism and rejection. The patient with a schizoid personality is beyond desire. Some people have argued that this judgment cannot be made reliably and depends on inference. They suggest that the two conditions be combined. This may become necessary, but my own clinical impression is that it is well worth trying to distinguish the two disorders. The avoidant and schizoid patients are likely to be markedly different in their family history, predisposition to schizophrenia, ability to form therapeutic or other relationships, and need for the response to treatment.

There was also a dispute involving the use of the word "schizoid." In earlier drafts of *DSM-III*, it was replaced by the term "introverted," but this was quite upsetting to Jungian analysts and factor psychologists, for whom "introverted" does not imply the presence of disorder and is, rather, a normal type. Some people felt that the motivation beneath the avoidant personality disorder should have been defined more broadly to include fears about shame, humiliation, losing control, and making a fool of oneself. The patient with an avoidant personality is often likely to meet the criteria for the dependent personality; once a relationship is formed it is clung to tenaciously.

Narcissistic Personality Disorder

This is a new category whose necessity was suggested by an increasing psychoanalytic literature and by the isolation of narcissism as a personality factor in a variety of psychological studies. The distinguishing

features in a psychoanalytic definition of narcissistic character might include 1) deficits in libidinal object constancy, 2) an incomplete internalization or maturation of psychic structures and regulatory mechanisms, particularly those having to do with self-esteem, and 3) aberrant or immature grandiosity. In making this diagnosis, the psychodynamic clinician might assess whether the patient experiences others as fully realized and separate objects or as self-objects and whether the transference that evolves in treatment takes on either a grandiose or idealizing configuration. Unfortunately, it is difficult to put these concepts into a descriptive and operational form that can be applied in one or two interviews by psychiatrists who may not have psychodynamic training or inclination. Instead, the *DSM-III* criteria for narcissistic personality disorder define descriptive and behavioral features that require only limited inferences about psychic structures, object constancy, and motivations. It is not clear to what extent the descriptive and psychodynamic definitions correlate and whether they will select the same patient groups.

CONCLUSIONS

The two major innovations of *DSM-III*—the multiaxial system and the provision of specific diagnostic criteria—are significant contributions to improved diagnosis of personality disorders. The next step in improving reliability is a clearer specification, even if an arbitrary one, of the precise quantity of impairment that defines a disorder. In addition, the individual personality disorders themselves need to be studied in various ways. The current *DSM-III* clustering of criteria is primarily based only on clinical intuition and should be validated with large studies to determine how the various criteria cluster in actual patients. It will be interesting to learn whether certain of the current disorders are highly correlated with each other and could perhaps be collapsed or whether new combinations might emerge. It is not clear whether the current criteria will successfully define relatively homogeneous groups of patients, e.g., the borderline personality disorder may include patients on an affective disorder spectrum, others with problems of impulse control, others with a masochistic need for punishment, and still others with a deficient self-concept. The validation of personality types as well as the investigation of their relationship to other *DSM-III* disorders are important and fascinating areas for future research.

Self-Induced Water Intoxication in Schizophrenic Patients

BY WILLIAM O. SMITH, MD., AND MERVIN L. CLARK, M.D.

The authors report on 21 cases of self-induced water intoxication and cite 25 others in the literature. Three of their patients demonstrated at least temporary inappropriate antidiuretic hormone secretion, 3 were receiving a diuretic, and the other 15 appeared to have "pure" water intoxication. Fifteen patients were receiving a psychotropic medication. Self-induced water intoxication appears to be more common in schizophrenic patients than is generally realized and should be suspected in any schizophrenic patient who develops convulsions or coma. Hyperdopaminergic CNS activity may be involved, and the authors suggest a possible mechanism similar to that for tardive dyskinesia.

Since our initial report in 1962 (1) of self-induced oral water intoxication in 2 schizophrenic patients without other predisposing illness, 17 reports of this phenomenon involving 25 additional patients have appeared in the literature (2–18). Sixteen of these 27 patients suffered at least temporarily from the syndrome of inappropriate antidiuretic hormone secretion (SIADH); however, 11 of the patients were able to dilute urine in a satisfactory fashion and several of these 11 were shown to excrete a water load normally after recovery.

Since 1962 we have encountered 19 additional schizophrenic patients with self-induced water intoxication. Nine of these patients had suffered a total of 16 documented episodes of water intoxication. Hence, this problem is obviously more common than heretofore believed. Three of our 21 patients showed evidence of SIADH when first observed, 11 did not, and urinary data were not obtained on 4 patients with water intoxication. The other 3 patients were receiving a diuretic.

Normal individuals cannot induce water intoxication in themselves by maximal oral water intake. The mechanism that permits schizophrenic patients to do so remains unknown. Since most of our patients had been receiving antipsychotic drugs before or at the time of their episode of intoxication, the role of these agents (as well as the role of psychosis) must be considered in the etiology of this syndrome. However, some patients were receiving no medication at all before becoming water intoxicated.

PATIENT DESCRIPTION AND CLINICAL FINDINGS

Twenty-one patients with self-induced water intoxication form the basis for this report. We have observed 20 of these patients in our department since 1961, including the 2 patients reported in 1962. Eighteen of these patients were hospitalized on the medical service of Central State Griffin Memorial Hospital in Norman, Okla., 2 were at the Oklahoma City Veterans Administration Hospital, and 1 patient was made available to us courtesy of R. Corenblum, M.D., of the University of Calgary. Three patients had seizures when they were admitted to the hospital; the remainder developed symptoms of water intoxication as inpatients.

The clinical findings and laboratory results for these patients are summarized in table 1. The patients ranged in age from 31 to 63 years; 10 were women and 11 were men. The most frequent and important clinical findings were lethargy, disorientation, confusion, semicoma or coma, and seizures. The seizures were of the grand mal type. It should be stressed that a history of excessive water drinking could be obtained for only 10 of the patients; in the remaining 11 patients neither patient, relatives, ward attendants, nor nurses were able to determine whether the patient had a history of excessive water intake.

Fourteen patients were receiving an antipsychotic drug before the onset of water intoxication. One patient was receiving only an antidepressant, and 2 patients were receiving only a thiazide diuretic. Four of the patients were taking no medication that could be determined.

Received June 15, 1979; revised Nov. 30, 1979; accepted Jan. 9, 1980.

20	46	M	114	—	—	—	Trifluoperazine, thioridazine	Seizures, semicoma	1
21	44	F	113	—	—	—	Thioridazine	Seizures, disorientation	1

[a]No evidence of inappropriate secretion of antidiuretic hormone.
[b]Patient 7 had received a prefrontal lobotomy.

LABORATORY FINDINGS

On admission to the medical service, serum sodium concentration for the 21 patients ranged from 100 to 124 mEq/liter. In those patients in whom serum osmolality was measured, it ranged from 191 to 267 mosmol/liter. Urine specific gravity was below 1.005 in all but 2 of the 9 patients for whom it was recorded. In the 7 patients for whom both urine and serum osmolality were determined, 4 patients had a urine osmolality well below their serum osmolality. BUN was found to be 11 mg/100 ml or less in all patients. The white blood cell count was elevated in most patients and, in the absence of demonstrable infection, was considered a response to recent seizure activity. Four patients with symptoms, signs, and serum chemistries consistent with the diagnosis of water intoxication did not have urine concentration studies during the initial 12 hours.

In the 18 instances where water restriction was the sole method of therapy, the patients recovered clinically within 24 hours, after excreting large quantities of urine; 3 of these patients also received hypertonic saline. The following case reports illustrate the two most common types of water intoxication: "pure" water intoxication, which has an unexplained etiology, and water intoxication associated with SIADH.

CASE REPORTS

Case 1 ("pure" water intoxication). Patient 1, Ms. A, was a 49-year-old woman who had been diagnosed as having chronic paranoid schizophrenia and had had four previous admissions for water intoxication secondary to excess water drinking. She had been on a home pass for approximately 5 days and apparently had been doing reasonably well until the afternoon of admission, when she began having seizures. After 4–5 major motor-type seizures she was returned to the hospital bleeding from a large tongue laceration and was given 10 mg of diazepam in the emergency room. Her current medications were chlorpromazine, 200 mg t.i.d.; trihexyphenidyl, 2 mg b.i.d.; and imipramine, 25 mg t.i.d.

On admission Ms. A had a pulse of 100, a rectal temperature of 96°F, and a blood pressure of 108/83. She was semicomatose and responded to painful stimuli. Her head was normocephalic without evidence of trauma, and her optic discs were sharp. She had a large laceration on the left margin of her tongue. Her neck was supple, her lungs were clear, and she had a regular heart rhythm with a grade II/VI systolic murmur at the apex. Her abdomen was soft, and she had active bowel sounds with no palpable masses or organomegaly. Her extremities were free from edema or cyanosis. Her deep tendon reflexes were hypoactive but symmetrical; her Babinski's signs were normal on both sides, and she moved all extremities.

Serum electrolyte levels were as follows: sodium=119 mEq/liter, potassium=4.0 mEq/liter, CO_2=20 mEq/liter, chloride=88 mEq/liter, serum osmolality=231 mosmol/liter, BUN=13 mg/100 ml, and glucose=105 mg/100 ml. Her urine osmolality on admission was 79 mosmol/liter.

Ms. A was placed on fluid restriction of 500 cc per day. By the following morning, after passing 7500 ml of urine, she was alert, communicative, and taking oral feedings. That day her serum electrolytes were within normal limits: sodium=137 mEq/liter, potassium=4.5 mEq/liter, chloride=103 mEq/liter, CO_2=28 mEq/liter, and BUN=9 mg/100 ml. Her serum osmolality was 276 mosmol/liter. Her hematocrit was 42% and her white blood cell count was 12,300/mm^3.

Case 2 (SIADH). Patient 12, Mr. B, was a 39-year-old chronic schizophrenic man who was admitted to the medical service. He had been receiving no medication and had been noted to be drinking large amounts of water on the day before admission. He had vomited on the day before admission and several times early on the morning of admission. Mr. B had been found on the floor, unresponsive and incontinent of urine and feces.

Mr. B had a blood pressure of 120/80, a regular pulse of 60, a respiratory rate of 12, and rectal temperature of 98°F. He responded to painful stimuli and occasional voice commands. His pupils were dilated but equal, round, and reactive. He had multiple conjunctival petechiae. His fundi were normal and had sharp disc margins. His oropharynx and tympanic membranes were clear. His neck was supple. There was a red, papular eruption over his anterior chest and shoulders. His lungs were clear, except for occasional rhonchi. Cardiac examination revealed a normal sinus rhythm without murmur. His abdomen was soft without palpable masses, and his bowel sounds were active. Ecchymoses were noted on Mr. B's arms where he had been held. During the neurological examination Mr. B responded to painful stimuli; his deep tendon reflexes were 2+ and symmetrical without positive Babinski's or Hoffman's signs. Cranial nerve functions II–XII appeared to be grossly intact.

Laboratory studies on admission revealed the following: serum sodium=117 mEq/liter, serum potassium=3.6 mEq/liter, CO_2=24 mEq/liter, chloride=100 mEq/liter, BUN=8 mg/100 ml, and glucose=127 mg/100 ml. Serum osmolality was 229 mosmol/liter and urine osmolality was 243 mosmol/liter.

We felt that Mr. B was water intoxicated and restricted his fluids to 500 cc/day. Over the ensuing 48 hours he became responsive, and his serum sodium concentration rose to 130 mEq/liter and his serum osmolality to 258 mosmol/liter. Measurement of urinary output during this period could not be obtained.

DISCUSSION

The problem of self-induced water intoxication in mentally ill patients without other predisposing illness has now been reported in at least 27 patients in the American literature since the first case was reported by Barahal in 1938 (19). The cases of these patients are summarized in table 2. This is clearly not a rare phenomenon since we have now encountered an additional 19 such patients during the past 17 years. Indeed, water intoxication should be a major consideration in the differential diagnosis of seizure disorders that develop in any mentally ill patient, particularly one in a mental institution. None of our patients had any other illness, such as cardiac, hepatic, or renal disease, that could account for a dilutional state, and none received water other than orally. Three of the patients had been receiving a diuretic agent.

The experiences reported here and in the literature appear to identify at least three groups of patients:

1. Patients for whom the water intoxication has an unexplained etiology. Eleven of our 21 patients are in this category and 11 of the 27 patients cited in the literature would be so classified on the basis of serum and urine osmolalities. Urine osmolalities were not available in 7 of our cases in this category. We have chosen to accept a urine specific gravity of 1.004 or below as evidence of appropriately dilute urine (20–21) and have classified these 7 patients as having probable "pure" water intoxication (see table 1).

2. Patients who have at least a temporary in-

appropriate secretion of ADH. Three patients in the present series demonstrated findings compatible with this syndrome, and 16 patients in the literature would be so classified. Urine osmolality was not determined in 2 of our 3 patients, and they are classified as having probable SIADH on the basis of urine specific gravity.

3. Occasional patients in whom the syndrome may be precipitated by diuretic therapy. Only 3 of our patients could be considered in this category, and only 3 patients of this type have been reported by other authors.

Urinary studies were not performed on our other 4 patients, but the clinical evidence for water intoxication, including serum osmolality, was compatible with the diagnosis (see table 1).

None of our patients manifested clinical evidence of overhydration (edema, papilledema, etc.) other than symptoms of cerebral edema. This has also been true of most patients reported in the literature, although a patient reported by Raskind and associates (10) died of cerebral edema with brain herniation, and Rendell and associates (18) recently reported 2 patients who died because of compulsive water drinking, 1 of whom was found at autopsy to have pulmonary edema.

In most of our patients it has not been possible to determine the cause of their high water intake. Some stated that they were attempting to wash out worms, other creatures, foul material, or cancer. In 1 reported case the patient stated that she was told by God to drink large quantities of "holy water." Other patients have stated they were cleansing themselves from sin.

All but 6 of our patients were receiving psychotropic medications before developing water intoxication. Little relevant information is available concerning the effect of these pharmacologic agents on salt and water metabolism. Ajlouni and associates (6) suggested that thiothixene is a possible stimulus for SIADH in a manner similar to other drugs such as chloropropamide, carbamazepine, and cyclophosphamide. This suggestion is based on well-documented observations of a case that they challenged and restudied with the use of water loading. Amitriptyline, thioridazine, fluphenazine, and haloperidol have also been linked with water intoxication associated with SIADH, but they have not been studied well enough to implicate them etiologically. They have also been associated with water intoxication without accompanying SIADH. On the other hand, reserpine and chlorpromazine, although associated with the development of water intoxication, have not been implicated in producing SIADH per se. Dyball (22) offered evidence from animal studies indicating effects of various phenothiazines on ADH that varied according to the structure of the side chain at position 10. He demonstrated that chlorpromazine with a three-carbon straight side chain inhibits ADH release, while promethazine with a branched two-carbon side chain stimulates ADH release.

How thiothixene fits into this concept with its three-carbon piperazine side chain structure is not clear. The fact that all of the neuroleptic drugs lower seizure threshold, are anticholinergic, and are dopamine blockers may be more important. Dubovsky and associates (3) suggested that the development of an acute psychotic episode per se, or some consequence thereof, may be the stimulus for ADH secretion. They pos-

tulated a possible autonomic pathway for this stimulation. Raskind and associates (10) hypothesized that the clinical triad observed in their 3 patients—psychotic depression, inappropriate secretion of ADH, and excessive water ingestion (thirst?)—represents a syndrome caused by or associated with disturbed CNS function, particularly dopaminergic hyperactivity. In other words, they suggest a hypothalamic mechanism rather than an autonomic one. To support this they point out the close anatomic proximity of the centers regulating thirst and ADH release and their interconnections with the limbic areas involved with emotions and primitive behavior; they cite evidence from animal studies that indicates the particular importance of dopamine as a neurotransmitter in regulating ADH release and extracellularly stimulated thirst. For example, destruction of hypothalamic dopaminergic pathways abolishes central receptor-induced ADH release (23) and produces adipsia (24); haloperidol, a potent dopamine receptor blocker, also inhibits thirst when injected centrally (preoptic area) (25). On the other hand, dopamine injected into the lateral cerebral ventricle effectively stimulates thirst (25) and when injected into the nucleus accumbens stimulates release of ADH (23). Considering the importance of the catecholamine neurotransmitters in regulating and modulating behavior, it is not difficult to visualize how hyperdopaminergic activity might explain the triad.

One could also speculate about an additional step. Schizophrenia is hypothesized to be associated with absolute or relative cortical hyperdopaminergic activity involving mesolimbic and mesocortical tracts (26). When a patient is treated with drugs that block dopaminergic activity, various aberrations of thirst, drinking behavior, ADH secretion, and other dopaminergic-dependent CNS functions could occur. Consistent with this speculation is the knowledge that nearly all the drugs used to treat schizophrenia have anticholinergic properties capable of producing a dry mouth and throat in man and consequent thirst. These drugs also lower the seizure threshold, thereby rendering patients more susceptible to seizures and perhaps rendering them more likely to have seizures as a result of minimal cerebral edema. However, by blocking dopamine receptors in the hypothalamic areas these drugs would tend to turn off or turn down thirst and to inhibit ADH release; therefore, the drugs, for the most part, by their primary central actions would not produce the water intoxication syndrome with or without inappropriate ADH secretion.

On the other hand, increased thirst and increased ADH release, depending on which receptors are most affected, are possible if a mechanism similar to that hypothesized for tardive dyskinesia is invoked for the dopamine-sensitive cells in the centers that regulate thirst and ADH release. Antipsychotic drugs, by blocking the postsynaptic dopamine receptors, may 1) pharmacologically and functionally denervate these postsynaptic neurons and render them supersensitive (denervation supersensitivity), while 2) simultaneously increasing presynaptic neuronal secretion of dopamine through feedback mechanisms around the block (27). With increased amounts of dopamine impinging on supersensitive cells, the resulting increased dopaminergic activity in the thirst and ADH-release centers could thereby account for the increased thirst and/or ADH release necessary to produce water intoxication. This could occur either as a breakthrough phenomenon while the patient is still taking drugs or a tardive phenomenon when drug treatment is stopped.

Whether ADH or thirst, or both, are affected in this process would depend on individual vulnerability and could thereby account for water intoxication without inappropriate ADH secretion for many of the subjects described in the literature and in this report. In addition, as in Raskind and associates' patients (10), the mechanisms (whatever they may be) that underlie the presumed hyperdopaminergic cortical activity and produce the signs and symptoms of schizophrenia might account for the episodes of water intoxication in the schizophrenic patients who have never had the benefit of treatment with neuroleptic drugs.

Three schizophrenic patients have also been reported to develop water intoxication when given a thiazide diuretic (28, 29). Three of our patients also developed the problem after thiazide administration. Since thiazide diuretics decrease free water clearance, it is quite likely that they contributed to and intensified the dilutional state in these patients during periods of massive water intake.

Mack, M.D., Professor of Psychiatry, Harvard Medical School at the Cambridge Hospital, 1493 Cambridge St., Cambridge, MA 02139.

The Prediction of Dangerous Behavior in Emergency Civil Commitment

BY ETHAN S. ROFMAN, M.D., CLIFFORD ASKINAZI, M.D., AND EMILY FANT

The authors compared the records of 59 psychiatric patients involuntarily committed to a Veterans Administration hospital on an emergency basis with those of a control group of 59 psychiatric patients with respect to the number of assaults noted during the first 45 days of hospitalization. The committed group had a .41 probability and the control group a .08 probability of committing an assault. The difference between the two groups was mainly accounted for by assaults that occurred during the first 10 days of hospitalization. The occurrence of an actual act of battery before admission did not predict assault in the hospital to a greater degree than did a verbal threat. The authors conclude that short-term clinical predictions of dangerousness predict assaultiveness in the hospital to a significant degree.

The need and justification for emergency involuntary psychiatric hospitalization is currently a subject of concern for lawyers, psychiatrists, and social scientists. According to *Psychiatric News* (1), in *Mathew v Nelson* a three-judge panel of the federal appeals court in Illinois commented on the limited number of current statistical studies in the area of dangerousness prediction. They stated,

> No study has attempted to measure the extent to which the predictability of dangerousness is enhanced by a history of a recent overt act. . . . No study called to our attention attempts to measure the incidence of violent behavior in a sample population of persons civilly committed for dangerousness (1).

The judges in this case upheld the current Illinois standards for emergency commitment, which do not require an overt act or threat of dangerousness to self or others for involuntary civil commitment. Decisions by federal courts in other states, however, have held that for emergency commitment to be constitutional the threat of danger to others must be imminent and substantial, as evidenced by a recent overt act, attempt, or threat (2). At least one state now specifically provides that a threat alone does not constitute grounds for commitment (3). These legal decisions all question the psychiatrist's ability to forecast dangerousness and call for further study of those circumstances which might permit at least some predictive accuracy under special conditions.

Monahan (4, 5) has discussed the problems inherent in prediction research, pointing specifically to the need for data concerning the accuracy of forecasts made in emergency settings. Monahan hypothesized that in such settings the small temporal "gap" between initial and outcome behavior should theoretically allow for greater predictive accuracy than has been possible to date. He postulated that there is a qualitative difference between forecasts of violence made in the community for the purpose of emergency commitment and those reported in the current literature, which involve judgments made primarily on institutionalized patients or prisoners for the purpose of deciding eventual release.

In this study, we undertook a retrospective review of commitment papers and hospital records to determine the predictive accuracy of community psychiatrists' clinical judgment of potential dangerousness in an emergency setting. The frequency of recorded in-hospital assaultive episodes of psychiatric patients committed on an emergency basis for likelihood of harming others was compared with that of a sample of psychiatric patients admitted to the hospital for all other reasons. We also determined the probability of assaultive behavior occurring in the hospital given the absence or presence of a recent overt violent act in the community, the number of days following admission that assault was most likely to occur, and the relationship of paranoid schizophrenia as a diagnosis to assaultive behavior.

METHOD

We obtained the records of all psychiatric patients admitted to our hospital with emergency commitment status from January 1, 1977, to June 30, 1978, and re-

Received May 17, 1979; revised Dec. 17, 1979; accepted Feb. 8, 1980.

viewed the Massachusetts Department of Mental Health Form 5A in each record. This form (the "temporary care paper") requires the applicant to state that in the opinion of the examiner (who is most often a psychiatrist in the community who was not chosen by the patient and whom we did not select for ability to predict dangerousness), the patient requires hospitalization to avoid the likelihood of serious harm by reason of mental illness. Written evidence must be presented supporting this opinion. The form includes the legal definition of "likelihood of serious harm," which is

> 1) substantial risk of physical harm to the person himself as manifested by evidence of threats of, or attempts at, suicide or serious bodily harm; 2) a substantial risk of physical harm to other persons as manifested by evidence of homicidal or other violent behavior or evidence that others are placed in reasonable fear of violent behavior and serious physical harm to them; or 3) a very substantial risk of physical impairment or injury to the person himself as manifested by evidence that such person's judgment is so affected that he is unable to protect himself in the community and that reasonable provision for his protection is not available in the community.

From 108 records initially obtained, we selected for further study 59 (54%) in which the reason for hospitalization given was risk of physical harm to others. We then searched the progress notes in these records for assaultive incidents noted during the 45 days following hospital admission. Such incidents were rated for severity on a 1+ to 4+ scale. The scale was divided as follows: 1+ was a serious assaultive threat that led to no action, 2+ was a threat that generated sufficient staff anxiety to lead to restraint, 3+ was an act that required immediate direct physical intervention by staff or patients to prevent a battery, and 4+ was an act involving a completed battery. We recorded the hospital day on which the incidents took place and the primary *DSM-II* admission diagnosis made by our hospital psychiatrists. The 59 records were further sorted into two groups on the basis of whether or not an actual act of violence was noted on the temporary care paper. The number of patients in each group was then compared to determine the probability of each group's being assaultive in the hospital.

Fifty-nine unmatched consecutive records of psychiatric patients admitted voluntarily or committed to the hospital in April and May of 1978 for reasons other than threat of harm to others were then reviewed; these patients constituted our control group. Fifty-four of these patients were voluntary and 5 were committed. Patients in both experimental and control groups were given psychiatric diagnoses and treated in the hospital by the same staff on the same two 30-bed units, which used a combination of milieu therapy, pharmacotherapy, group therapy, and individual psychotherapy. Both units are usually locked.

TABLE 1
Diagnoses of 59 Patients Committed for Dangerousness and 59 Control Patients

Diagnosis	Committed Group N	Committed Group %	Control Group N	Control Group %
Psychotic organic brain syndrome	3	5.1	0	
Schizophrenia, hebephrenic	0		1	1.7
Schizophrenia, catatonic	2	3.4	0	
Schizophrenia, paranoid	19	32.2	16	27.1
Schizophrenia, acute episode	1	1.7	5	8.5
Schizophrenia, latent	1	1.7	0	
Schizophrenia, schizoaffective	4	6.8	2	3.4
Schizophrenia, chronic undifferentiated	13	22.0	11	18.6
Manic-depressive illness	6	10.2	6	10.2
Psychotic depressive reaction	0		2	3.4
Neurosis	1	1.7	5	8.5
Personality disorder	1	1.7	4	6.8
Alcoholism	8	13.6	5	8.5
Transient situational disturbance	0		2	3.4

RESULTS

The average age of the patients in the experimental group was 38.5 years; in the control group the average age was 37.6. Both groups were composed of 57 men and 2 women. The mean length of stay for the experimental group was 45.5 days (median, 27 days); for the control group the mean stay was 29.9 days (median, 22 days). The diagnoses of the patients in both groups are presented in table 1.

Twenty-four (41%) of the 59 emergency committed patients carried out 52 separate incidents of assault in the hospital. Five (8%) of the 59 control group patients carried out 16 assaultive incidents. The difference between these numbers of patients was significant ($\chi^2=16.504$, $p=.00005$).

The actual number (and percent) of assaultive incidents that were scored 1+, 2+, 3+, and 4+ on our scale was 16 (30.8%), 14 (26.9%), 9 (17.3%), and 13 (25.0%), respectively, for the experimental group and 8 (50%), 2 (12.5%), 0, and 6 (37.5%), respectively, for the control group. Five of the 6 assaultive incidents that were scored 4+ in the control group were carried out by 1 patient.

For 30 of the 59 emergency committed patients, a specific violent act was noted on their emergency commitment form, for 23 no act was noted, and for 6 the data were insufficient to make a determination. Thirteen of the 30 (43%), 9 of the 23 (39%), and 2 of the 6 (33%) people went on to assault somebody after they were hospitalized. There was no significant difference between the patients who had actually acted violently and those who had not with respect to the number of patients in each group who committed assault in the hospital ($\chi^2=.09$, $p=.76$).

The greatest frequency of incidents of assault for both the emergency committed group and the control group occurred within the first 10 days of hospitalization. During this interval 24 committed patients car-

ried out 39 violent incidents and 5 control patients carried out 8. During the next 10 days the committed patients carried out 7 violent acts and the control patients carried out 2. From day 20 to day 40 each group was responsible for only 3 acts.

We also determined the relationship of the diagnosis of paranoid schizophrenia to assaultive behavior rated as 4+. The records of all paranoid schizophrenic patients in the experimental group and the control group were compared with those of all other patients in both groups with respect to the completion of assaultive acts noted 4+. The 6 patients with a diagnosis of paranoid schizophrenia who committed such violent acts represented 16.2% of the 37 patients with this diagnosis. The 4 patients with all other diagnoses who committed such acts represented 4.9% of the 81 patients with other diagnoses. The difference between the number of paranoid schizophrenic patients and those with all other diagnoses who committed acts with a rating of 4+ was significant (χ^2=4.1649, p=.0413).

DISCUSSION

This preliminary retrospective study indicates that the clinical determination of dangerousness by physicians who send people to a typical psychiatric Veterans Administration medical center for emergency psychiatric commitment predicts the patients at risk of in-hospital assaultive behavior to a statistically significant degree. In the group of patients who were committed to the hospital on an emergency basis the incidence of all assaultive episodes was 41% and for acts of battery alone was 13% in 45 days. This compared with an incidence of 8% and 3% in a control group of psychiatric patients. This finding supports the hypothesis that predictions of dangerous behavior have validity when the time of prediction and the time of validation are relatively close together.

Our results indicate that the history of a recent overt assaultive act as noted on an emergency commitment paper and the physician's clinical assessment of potential dangerousness in the absence of an overt act predict assaultiveness in the hospital to about the same degree. Therefore, an overt act of assault should not be a requirement for emergency commitment.

The ability to predict when assaultiveness in the hospital is most likely to occur is important from a clinical point of view. There is often staff pressure to keep a patient who commits an assault in a maximum security setting for an indefinite length of time. Information as to when patients who commit a single episode of assault are actually likely to stop being violent would help clinicians to know when such patients should be transferred to less restrictive settings. The data presented here indicate that patients who were thought harmful before admission are about as assaultive as all other patients after 20 days of hospitalization.

Patients with a diagnosis of paranoid schizophrenia in this study were responsible for roughly an equal number of all assaultive episodes and a statistically significant number of acts rated most violent during the 45 days after admission to the hospital. These paranoid patients were all men under the age of 45, and often they were also responsible for a series of acts rated most violent that continued to occur beyond the 45-day cutoff point of the study. These results support the conventionally held viewpoint that younger paranoid schizophrenic patients tend to be more dangerous than other patients in a large psychiatric hospital.

It should be noted that our control group was probably more dangerous than the general population: it contained paranoid schizophrenic patients. Therefore, any comparison with respect to risk ratios, such as the 41%:8% we found, considerably understates the dangerousness of the committed group. Furthermore, all of the assaults in our study took place in a structured hospital setting where attempts to understand feelings, opportunities for ventilation, and the ability to control aggressive behavior were apparent. All patients in both groups were receiving adequate doses of appropriate antipsychotic medication. It is likely, therefore, that the probability of the patients in our experimental group (who would be unmedicated outside the hospital) committing assaults in the community would have far exceeded 41% without emergency commitment.

Monahan and Wexler (6) pointed out that when a psychiatrist makes a prediction of dangerousness without further specifications, he or she is making at least three separable assertions:

1. The individual being examined has certain characteristics.
2. These characteristics are associated with a certain probability of violent behavior.
3. The probability of violent behavior is sufficiently great to justify preventive intervention.

The first two of these assertions are subject to various "standards of proof"; the third is essentially a social policy trade-off decided in the political process.

Our research basically addresses the second of these assertions and is an attempt to obtain empirical data concerning the probabilities involved in short-term prediction. We would agree with those who hold that many people ignore important differences between populations in degree of dangerousness and by so doing wrongly fail to consider respectable empirical correlations (7). This often occurs when there is confusion with respect to dangerousness as a probability statement, dangerousness as a social policy decision, and dangerousness as an individual outcome.

As a result of this confusion, critics of psychiatry have often been given a free hand in imposing on the public their own, often covert, social cost analysis. This operation has been characterized by an exclusive emphasis on implicit social cost comparisons in one direction only (false positives) and by a unilateral re-

definition of the prediction problem from one involving probabilities to one involving individual outcomes.

Given the social cost of a brief deprivation of liberty for those who are not fully dangerous (because dangerousness is not an all-or-nothing variable) versus the social cost of death or injury to victims of people not committed on an emergency basis, we believe our study demonstrates sufficient predictive accuracy to justify the use of brief emergency commitment. It further indicates that patients committed on an emergency basis are likely to harm staff and other patients until their psychoses have been diagnosed, treated, and brought under adequate control. These patients should, therefore, be treated with care, respect, and adequate staffing.

Foundations' Fund Prize for Research in Psychiatry

The American Psychiatric Association takes pleasure in inviting submissions for the fourth annual Foundations' Fund Prize for Research in Psychiatry.

Candidates for this prize should be citizens of the United States or Canada and should be nominated by a sponsor. Sponsors should be members of the American Psychiatric Association. Members of the prize board are excluded from submitting nominations.

The *sponsor* should submit a supporting letter justifying the nomination in detail and summarizing the research accomplishments of the nominee.

The *nominee* should submit:

1) An up-to-date curriculum vitae;
2) An up-to-date bibliography;
3) A single paper or book or a group of representative, and thematically linked, papers or books published (or accepted for publication) in English and dated within ten years prior to the deadline of submission;
4) A summary statement written by the nominee, emphasizing the principal theme (or themes) of the work and its internal cohesiveness and consistency.

Six copies of each entry should be submitted to Joel J. Elkes, M.D., Chairman, Foundations' Fund Prize Board for Research in Psychiatry, American Psychiatric Association, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Entries will be acknowledged but cannot be returned. The award will be presented at the Convocation of Fellows at the 1981 APA annual meeting.

The deadline for submission is November 1, 1980.

The Mental and Nervous Disorder Utilization and Cost Survey: An Analysis of Insurance for Mental Disorders

BY O.B. TOWERY, M.D., STEVEN S. SHARFSTEIN, M.D., AND IRVING D. GOLDBERG, M.P.H.

The Mental and Nervous Disorder Utilization and Cost Survey in Washington, D.C., has yielded useful information about outpatient utilization within an insurance plan with broad mental health coverage, as well as evidence that a comprehensive benefit with a low deductible and copayment can be offered and reasonably utilized. From the results of this survey and a substudy of claims made during 1977, the authors conclude that psychiatric diagnostic information submitted on insurance claim forms may often be inaccurate, primarily because of providers' concerns about confidentiality; such information is of little use for peer review or claims review. The authors state that caution must be exercised in generalizing from the experience under this plan to speculate about outpatient utilization which might result from broad coverage on a national level.

The Mental and Nervous Disorder Utilization and Cost Survey (MANDUCS) is a statistical aggregation of all outpatient claims in one year for patients in the Washington, D.C., area who are covered by the Government-Wide Service Benefit Plan, usually referred to as the Blue Cross and Blue Shield Federal Employee Program (FEP). It represents the first large-scale survey of primarily office-based private practice using insurance claims forms as the input data. The utilization experience is especially important since FEP offers one of the most comprehensive mental health benefits in the nation. After a deductible of $100 or $200, depending on whether the coverage is high option or low option, 80% or 75% of usual and customary charges for all outpatient psychiatric visits is covered, the only limit being a lifetime maximum of $50,000. Services can be provided by either psychiatrists or psychologists as independent practitioners and by psychiatric nurses and social workers if they receive physician supervision.

As a body of data MANDUCS can be used to compare the mental health professions along a number of variables related to utilization and can be used to assess relationships among persons served, visits made, and costs (charges) for services. One of the original aims of the study was to permit the development of statistical patterns of utilization and costs to be used as a basis of comparison for selected or sampled individual cases by the insurance carrier for claims review or by local professional societies for peer review. However, because of evidence generated by the study (discussed below) that the diagnostic information submitted is of questionable accuracy, the information provided by the study is of only limited value for claims and peer review based on diagnosis. In this paper we will review the findings of the study and discuss implications of the data.

HISTORY OF MANDUCS

In 1975 there were cutbacks in psychiatric benefits in the two major plans participating in the Federal Employees Health Benefits Program; benefits in these two plans had been expanded in 1967 to be virtually unlimited and equivalent to general health care coverage. The second largest plan, the Government-Wide Indemnity Benefit Plan sponsored by the Aetna Insurance Company, which had experienced high psychiatric costs, cut outpatient coverage to an annual limit of 20 visits in a private office and 40 visits in a qualified community mental health center. In the "open" season a large number of Aetna enrollees with psychiatric claims switched to Blue Cross and Blue Shield (1). After initially proposing a similar major cutback in coverage, Blue Cross and Blue Shield instead introduced a lifetime maximum of $50,000 for mental disorders under its supplemental benefits. Further, they promised the Civil Service Commission that they would increase their efforts to review and account for the high expenses associated with psychiatric treatment.

In February 1975 the national office of Blue Cross and Blue Shield sent a new form, called the Mental

Presented at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12-18, 1979. Received May 18, 1979; revised Dec. 12, 1979; accepted Feb. 8, 1980.

From the Office of the Administrator, Alcohol, Drug Abuse, and Mental Health Administration (Dr. Towery), the Division of Mental Health Service Programs, National Institute of Mental Health (Dr. Sharfstein), and the Division of Biometry and Epidemiology, National Institute of Mental Health (Mr. Goldberg).

Opinions expressed herein are those of the authors and do not necessarily reflect the official policy of the Alcohol, Drug Abuse, and Mental Health Administration.

Health Report Form, along with guidelines for nervous and mental disorders to the local Blue Cross and Blue Shield plans that administer the FEP. The instruction to the local plans stated, "It is imperative that we strengthen the review process in our efforts to administer the Federal Employee Program's nervous and mental benefits in a manner consistent with appropriate utilization. We believe it is necessary that Plans implement these guidelines in their claims review."[1] In the Washington, D.C., area the local plan, Group Hospitalization, Inc., delayed introducing the Mental Health Report Form to allow for provider input and to design the statistical survey known as MANDUCS.

Why was the Washington, D.C., area chosen for special study? In 1973 the Blue Cross and Blue Shield FEP-covered population in the Washington area represented 21% of the total FEP enrollees nationwide but included 32% of those persons treated for mental disorders and accounted for 36% of the total mental disorder benefit costs incurred. Under Aetna, residents in the Washington, D.C., area constituted 17% of total Aetna enrollees but accounted for 48% of the total mental illness benefits incurred. Whereas the combined Aetna and Blue Cross and Blue Shield mental health care costs comprised about 8% of the two plans' total health care costs nationwide, in the Washington, D.C., area the portion was almost 15% of the total. Further, the data indicated that the Washington, D.C., area accounted for a very high proportion of the larger claims—that is, 38% of all mental disorder claimants each of whom had total outpatient claims of over $7,000 in 1973. Due to these high expenses, a study of the Washington, D.C., area's patterns of utilization and cost, which could augment claims review and peer review, was of highest priority (1).

The provider community in Washington, including psychiatrists, psychologists, psychiatric nurses, and social workers, is large and well-organized. The introduction of the Mental Health Report Form, which asked for a diagnosis, symptom check, and estimate of degree of impairment, occasioned strong comment and protest. Many federal employees feared breaches of confidential information to employer or outside groups. It took 18 months for the provider organizations and Blue Cross and Blue Shield, meeting under the auspices of the Civil Service Commission and the National Institute of Mental Health, to agree to the introduction of the report form and the design of MANDUCS. After the form was introduced in the summer of 1976, many consumers and providers confused the Mental Health Report Form and augmented claims review with the statistical aggregations for MANDUCS. They protested to the Civil Service Commission, the Congress, and the Mental Health Law Project. Blue Cross and Blue Shield withdrew the form after one year of use and substituted a requirement for an itemized bill that included a diagnosis classifiable under *DSM-II*. The MANDUCS Advisory Committee, made up of representatives of the mental health professional associations, the Mental Health Association (a citizens' group), the insurance carriers, NIMH, and the Civil Service Commission, continued to meet and advise on the project. The experience with the Mental Health Report Form in Washington, D.C., is an important case study of the acceptability and usefulness of such a form for claims review.

DATA COLLECTION

MANDUCS comprises a statistical aggregation of six months (January–June) of report forms and six months (July–December) of itemized bills for individual and group psychotherapy collected for calendar year 1977. Insurance forms and itemized bills were abstracted and placed in an anonymous automated data file. The study included supplemental claims and excluded basic benefits. This meant that all outpatient care was included, but inpatient care was not. Because, with only minor exceptions, this survey was based on claims submitted for payment rather than on service actually rendered, there are several important points to bear in mind in interpreting the data. First, since there is a $100 or $200 deductible under supplemental claims, individuals who were seen only once or twice and did not submit claims are not included in the survey (other studies [2] have indicated that this group may comprise as much as one-third of all psychiatric outpatients). To some extent the amount claimed might have been influenced by the fact that the maximum amount payable for each visit varied by type of provider, with psychiatrists receiving a maximum of $45 per visit, psychologists $40, social workers $30, and nurses $20. Finally, patients who never submitted claims for services received because of concerns about confidentiality or other reasons would of course not be included in this survey.

Throughout the next section, in which the findings of the survey are presented, it is important to keep in mind that some individuals were seen by different types of therapists or received different diagnoses at different visits. Thus, the summation of patients across provider types or across diagnostic groupings results in a duplicated count of individuals.

A final caveat about the data collected in this survey relates to the fact that some bills for treatment are not submitted until several months after the treatment is rendered. The cutoff date for collection of these data was extended to February 1978, but even so more bills came in throughout the rest of the year. Although there is no way to determine exactly what percent of the total claims for service in 1977 the MANDUCS

data represent, the Blue Cross and Blue Shield claims department estimates they account for approximately 80% of all claims for treatment rendered in 1977.

FINDINGS

Tables 1-5 present some of the major findings from the MANDUC survey. During the 1977 calendar year there were approximately 758,771 participants in the Washington, D.C., area Blue Cross and Blue Shield FEP. As can be seen from table 1, mental disorder claims were submitted during 1977 for 15,484 individuals (2% of the enrolled population), for a total of 506,451 outpatient visits. The total charges for these visits were $20,115,309, for an average of $1,299.10 per individual and $40.00 per visit. The cost of outpatient psychotherapy per enrollee was approximately $26.50 per year.

As can be seen in table 1, most patients were seen by psychiatrists, followed by psychologists and psychiatric social workers. Only a small proportion of patients were seen by psychiatric nurses and nonpsychiatric physicians. The proportion of visits claimed by each type of provider was similar, with psychiatrists making claims for 69.6% of the visits, psychologists 18.4%, social workers 11.6%, psychiatric nurses 0.3%, and nonpsychiatric physicians 0.2%.

Table 2 presents data on the percent of individuals with paid claims who made a specified number of visits to the indicated type of provider. Similarly, table 3 presents data on the percent of all visits to that provider type accounted for by those individuals. Table 3 shows that approximately one-half of all visits paid for were those of individuals who made 60 visits or less, and table 2 reveals that these individuals represented 84% of all subjects in the study. Stated conversely, nearly one-half of all visits paid for were for the 16% of individuals who made 60 visits or more in 1977. This situation, in which a small number of recipients use a large portion of services, is comparable to other medical benefits, especially those in the "catastrophic" category. In table 4 we see that these individuals accounted for more than one-half of all money claimed for the 1977 outpatient mental benefit.

It is important to note that although we may be able to conclude from these data that a small proportion of patients account for the majority of visits in any one year, we must be cautious about any inferences related to the extent to which intensive psychotherapy or psychoanalysis accounts for this. Because the only claims tabulated were those made for services received between January 1, 1977, and December 31, 1977, many individuals who either ended treatment early in 1977 or began treatment late in 1977 would have only a small number of visits claimed for 1977. For example, an individual beginning treatment on November 1 and receiving treatment 4 times each week would have only 32 visits tabulated for 1977 and would appear as one of the individuals receiving 32 visits or fewer in this study.

It can also be seen from table 3 that psychiatrists tended to have more claims for individuals with a large number of visits in 1977 than did the other types of providers. Although about 60% of the visits claimed by both the psychologists and social workers were for individuals with 50 visits or less, only about 40% of the visits claimed by psychiatrists were for such individuals. It is possible that some of this difference is attributable to the great number of psychoanalysts in the area.

For discussion purposes we have included in table 5 the distribution of diagnostic categories that were recorded on the claims which were paid. Although these

data are valid from the standpoint that they represent what was submitted on the insurance claims, we do not believe that they accurately reflect actual practice in the area. A substudy conducted by the Washington Psychiatric Society provided evidence that providers have submitted less "severe" diagnoses (i.e., more diagnoses of neurosis and transient situational adjustment reaction) because of legitimate concerns about confidentiality. For the substudy, area psychiatrists were asked to anonymously submit aggregate data on the numbers of FEP patients they saw in 1977 and their diagnoses, with no identifying patient information.

TABLE 5
MANDUC Survey Data on the Number and Percent of 15,484 Individuals with a Specified Diagnosis of Mental Disorder on Claims by All Providers in 1977

	Individuals with Diagnosis	
DSM-II Diagnosis	Number[a]	Percent
Schizophrenia	821	5.3
Affective disorders	474	3.1
Psychotic organic brain syndrome	32	0.2
Neuroses	12,742	82.3
Personality disorders	1,585	10.2
Alcoholism	145	0.9
Drug dependence	17	0.1
Psychophysiologic disorders	182	1.2
Transient situational disorders	1,892	12.2
Nonpsychotic organic brain syndrome	36	0.2
Mental retardation	11	0.1
All other diagnoses	858	5.5

[a]Numbers total more than 15,484 because some individuals received more than one diagnosis.

Diagnoses seen in the Washington Psychiatric Society study were much more evenly distributed across diagnostic categories then those in the MANDUC survey, and the distribution more closely resembles that found in other studies of private-practice psychiatry, such as the Joint Information Service study of 1975 (3). Because of this finding, we feel that tabulations such as numbers of visits and dollars claimed based on each diagnostic category are of little value for peer and claims review purposes unless mechanisms can be developed to collect these data separately from personal identifying information. We have therefore omitted these data from our presentation.

DISCUSSION

There is a paucity of knowledge about the utilization of outpatient mental health services in the private sector. Nonetheless, health insurers and others must make difficult decisions related to the types of services and service providers, as well as length and intensity of treatment, that should be covered. The MANDUCS data can be very informative when used alongside data from other studies of different populations in different treatment settings. However, we would like to caution about the extent to which these data can be used as a basis for speculation about the degree of utilization nationwide if the entire population were covered by an outpatient nervous and mental benefit as comprehensive as the Blue Cross and Blue Shield FEP. The Washington area is in many ways not typical of the rest of the country. There is a very dense concentration of mental health providers in the Washington area, probably as dense as or denser than any other area in the country. In general, the insured population is more highly educated and of a higher socioeconomic class than is found in most areas. Employment and other demographic characteristics of the insured, such as average age and family size, no doubt also affect the utilization patterns in this area.[2]

Given these considerations, it is probably safe to conclude that utilization under the FEP represents the most intensive utilization that might occur under such a comprehensive mental health benefit. Certainly the utilization is greater than has been reported in other studies of outpatient psychiatric practice (4).

Is the 2% of the enrolled population who use mental health services too high? Is the $26.50 charged per enrollee to pay for these services excessive? Questions such as these can only be addressed in the context of information not provided by a survey such as MANDUCS. In order to meaningfully discuss them, we must consider such factors as the effectiveness of the treatment in alleviating distress and improving the level of social and occupational functioning and the costs that would result if such treatment were not available. Ultimately, we must make decisions based on the value and importance that we attribute to providing psychotherapy as a means of treating mental disorders.

A final issue that merits discussion relates to any attempt to analyze utilization patterns of a health insurance benefit based on the data submitted on the claims form. This is the question of the accuracy of the data that are submitted. Here, the most important questions do not relate to fraudulent and abusive practices. Although there may be instances of such practices as upgrading (billing for services more extensive than those actually provided) and billing for treatment sessions not actually rendered (5), it is doubtful that any of these practices occur on a wide enough scale to greatly alter the utilization patterns that are inferred from the data collected. A study such as MANDUCS is not designed to detect such practices, for to do so would require the development of individual profiles of providers and patients.

The most questionable item submitted on FEP mental and nervous disorder insurance claims is the diagnosis. Even though many have questioned the usefulness of a *DSM-II* diagnosis in determining the appropriate length and intensity of psychotherapy, insurers have generally insisted that a *DSM-II* diagnosis be submitted as part of the routine claims procedure. Before the MANDUC survey was begun, two hypotheses were entertained relating to the accuracy of diagnoses submitted. The first was that mental health professionals, because of their desire to make sure that a patient perceived as needing therapy should not be denied coverage by the insurance carrier for some arbitrary reason related to diagnosis, might submit a more severe diagnosis such as schizophrenia in an attempt to assure continued treatment coverage. The second hypothesis was that fears about confidentiality might lead

[2]S.S. Sharfstein, B. Dean: Washington psychiatry—boom or bust? Presented at a meeting of the Washington Psychiatric Society, Sept. 1977.

providers to submit diagnoses perceived to be less severe because of the social stigma and negative connotations of many diagnoses.

From the results of the MANDUC survey it would appear that the former practice occurred rarely, if at all, simply because few diagnoses such as schizophrenia, manic-depressive psychosis, or even the personality disorders were submitted. Ninety-four percent of all diagnoses presented were for either neurosis or transient situational adjustment reaction. If these diagnoses are inaccurate, we feel that it is probably due to providers' concerns about confidentiality. Such diagnostic information is of little use for peer review or claims review unless mechanisms are developed to collect it without personal identifying data. Such a system, developed by the Washington Psychiatric Society, has been described elsewhere (6).

OPINION AND COMMENT

"Medical Responsibility" in Institutional Settings

BY BEN BURSTEN, M.D.

The economics of institutional delivery of mental health care sometimes makes it impossible for psychiatrists to meet the demands of medical ethics. At times the psychiatrist's signature is used to imply a degree of medical responsibility that is not justified or a degree of supervision of less highly trained personnel that has not been given. The continuing variance between psychiatry's ethical precepts and its practice in some institutions creates an undesirable situation. The author examines several options and concludes that the ethics should be rewritten. Dr. Frederick J. Stoddard comments on the author's presentation.

Henry Tucker, a prisoner in the state of Virginia, recently won a lawsuit charging that antipsychotic drugs were administered to him improperly. Although the suit centered around extensive neurological damage, pertinent to the complaint were the facts that the medications were ordered by a nonphysician and the orders were countersigned by physicians. The countersigning physicians had not performed a complete examination of Mr. Tucker. According to *Psychiatric News* (1), the physicians' direct contacts with Mr. Tucker were confined to rounds, during which "he (Tucker) would be seen but insofar as hands-on procedure, no. We would be seeing, ordinarily, pass the amenities, 'How are you today?' . . . and then go on to the next." The expert witnesses for the plaintiff stressed the impropriety of delegating responsibility to people who were not qualified. Decisions such as the Tucker case should arouse the greatest concern throughout our profession.

DIFFERENCES BETWEEN PRINCIPLES AND PRACTICE

Consider the *Principles of Medical Ethics* promulgated by the American Medical Association in 1957 and annotated and revised with reference to psychiatry by the American Psychiatric Association in 1978 (2). Section 6 of the *Principles* states, "A physician should not dispose of his services under terms or conditions which tend to interfere with or impair the free and complete exercise of his medical judgment and skill or tend to cause a deterioration of the quality of medical care" (2, p. 3). The annotations for section 6 continue,

> In relationships between psychiatrists and practicing licensed psychologists, the physician should not delegate to the psychologist or, in fact, to any nonmedical person any matter requiring the exercise of professional medical judgment. . . . When the psychiatrist assumes a collaborative or supervisory role with another mental health worker, he/she must expend sufficient time to assure that proper care is given. It is contrary to the interests of the patient and to patient care if he/she allows himself/herself to be used as a figurehead. . . . In referring patients for treatment, counseling, or rehabilitation to any of these practitioners, the psychiatrist should ensure that the allied professional or paraprofessional with whom he/she is dealing is . . . competent to carry out the therapeutic task required. The psychiatrist should have the same attitude toward members of the medical profession to whom he/she refers patients. (1, p. 7)

I submit that in many institutional settings this precept is largely ignored.

Based on an Issues Workshop of the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12–18, 1979. Received May 14, 1979; revised Nov. 27, 1979; accepted Jan. 9, 1980.

Often in institutional settings patients theoretically under our care are seen primarily by personnel other than psychiatrists. It is not uncommon that the treatment plans we sign are carried out in significant part by master's level psychologists, bachelor's level social workers, and nurses who may or may not have a four-year college degree. Does our signature indicate that we have spent sufficient time to understand in detail what other team members will do? Does it indicate that we approve of or endorse these efforts, or is it sometimes a matter of compromise with the status aspirations of other personnel or a necessary medical-appearing validation that allows them to do whatever it is they do? I suggest that often the psychiatrist's involvement amounts to little more than providing a legalizing countersignature. Indeed, the sheer number of patients for whom some psychiatrists assume responsibility, especially in outpatient settings, often precludes either direct contact or meaningful supervision.

In institutional settings we work with whoever is on board. Sometimes our colleagues are superb; sometimes they are merely holding down a job—and this goes for medical as well as nonmedical colleagues. The psychiatrist is not in a position to select the colleague to whom he or she will refer. In most hospitals, each discipline has the autonomy to select its own staff, often without consultation with the other disciplines. This system makes a mockery of our ethical standard of assuming the competence of colleagues to whom we refer patients within an institution.

Section 7 of the *Principles* states, "In the practice of medicine, a physician should limit the source of his professional income to medical services actually rendered by him, or under his supervision, to his patients" (1, p. 3). Carrying this precept over to institutional settings, we are not talking about the source of the *physician*'s income but, rather, the source of the *institution*'s income billed in the name of the physician. It seems to me that the principle would be the same, and I submit that in many institutional settings this precept is largely ignored.

The criteria of adequacy of supervision have not been spelled out; however, much of what goes on in some large institutions is virtually unsupervised. The concept of physician-extenders is rapidly gaining acceptance as a viable dimension of health care delivery. However, "physician-extender" does not mean "physician-replacer," and at times what is billed as the former proves to be the latter. There may be instances in the delivery of health care when it is appropriate actually to replace the physician by a less highly trained person or a differently trained person. However, it is not always clear that third-party payers desire to reimburse for the services of unsupervised less highly trained personnel at the same rate that they would reimburse for physicians' services. When we ambiguously bill under the physician's name as if the services were provided or supervised by the physician, we may be violating section 7 of the *Principles of Medical Ethics*. That such practice occurs has been documented by Towery and Sharfstein (3). According to them, such practice may be more than violation of an ethical principle; it may be fraud. Even if it is not fraud (which implies intentionality), there may still be negligent misrepresentation.

When we consider billing practices we must be careful to distinguish the psychiatrist in his or her administrative role from the psychiatrist in his or her treatment role. As an administrator, the psychiatrist who signs a bill may be indicating only a certification that, to the best of his or her knowledge, the work was performed. As a treater, however, the psychiatrist who signs a bill seems to imply that the physician-signer has assumed medical responsibility and that whatever delegation may have occurred has been well supervised.

The annotation to section 10 of the *Principles* states that "it is unethical for a psychiatrist to offer a professional opinion unless he/she has conducted an examination" (1, p. 11). Although this guideline has reference to diagnosing public figures, it would seem all the more relevant as a guideline to diagnosis leading to treatment implications in terms of actual patients. I submit that in many institutional settings this precept is largely ignored.

At times psychiatrists countersign intake reports of patients whom they have not personally seen. They may sign treatment plans for patients whom they have not personally interviewed. Sound medical practice requires that a plan of treatment be initiated only after adequate diagnosis. Therefore, it follows that a psychiatrist who lends his or her name and weight of authority to a treatment plan implies that he or she is satisfied with and is endorsing the diagnosis. According to the precept of section 10 as annotated, this cannot be done at long distance.

Another practice that is relevant to "long distance" diagnosis is the use of routine and p.r.n. orders. Some so-called doctor's orders are routine to the point of being preprinted. When we order an injectable neuroleptic or seclusion "p.r.n. agitation," a diagnosis is required when the decision to employ the order is made. The nursing staff, at whatever level is allowed to give injections or place people in seclusion, diagnoses the existence of sufficient agitation and diagnoses the quality of the agitation in relation to its social surround to judge whether it requires this medical intervention. The decision of medical appropriateness (as contrasted with, for example, punitive appropriateness or inappropriateness) is not made by the doctor who signed the order. One might argue that the doctor made the initial assessment of the patient's volatility or lack of impulse control, but I have seen many admission work-ups with no evidence of volatility followed by routine orders for p.r.n. medications or restraints.

In large institutions, then, this diagnostic appraisal

is often delegated to less highly trained personnel with the doctor's signature given well in advance of the incident. In cases of acute emergency, few would quarrel with the use of restraint by anyone on the scene. However, the p.r.n. order is often carried out under the psychiatrist's authority in a somewhat less than emergency situation. It is difficult to see how the psychiatrist can have made an adequate diagnostic assessment before the agitation even occurred.

There are more appropriate p.r.n. orders in which the decision making is given to the patient himself or herself. Not infrequently we will give the patient sleeping medications and say, "Take one of these pills if you have trouble going to sleep." When the decision lies with the patient, the implication is that the psychiatrist has decided that the patient is capable, within limits, of regulating his or her medication. However, when the decision lies with someone other than the patient, there is a delegation of diagnostic authority that needs to be well thought through.

CAUSES FOR THE DIFFERENCES

Why are some of our institutional practices at variance with our ethical precepts? I do not believe that we psychiatrists are generally motivated by either avarice or malice. More often, institutional psychiatrists are forced into these practices by the politics and economics of the delivery system. *Psychiatric News* (4) quoted the late Browning Hoffman's definition of institutional psychiatry as "that mental health care delivery system in which massive numbers of patients are assigned to minimal numbers of often poorly trained professionals and are 'treated' by techniques and practices that further institutional as well as, and perhaps instead of, patient interests." Institutional psychiatrists simply do not have the time to adhere strictly to the ethical precepts.

I doubt that this numbers-bind will be resolved by deinstitutionalization programs. There is evidence (5, 6) that large numbers of people who are perhaps prematurely discharged from hospitals find their way into nursing homes, emergency rooms, underfunded and understaffed community mental health centers, and boarding homes subsidized by the welfare system. It should be clear by now that the so-called deinstitutionalization program is merely a transitionalization program: the patient frequently bounces from one doctor's delegated line of authority and responsibility to another's. The basic problem of medical responsibility in institutions persists; only the setting has changed.

Viewed in the transinstitutional context, then, it is probable that there has been no decrease in the institutionalized patient population. On the other hand, there is a serious person-power problem with regard to psychiatric providers. There may or may not actually be a decreasing average number of psychiatrists in community mental health centers (7, 8). More important than the actual number of psychiatrists per institution, however, is the question of what these psychiatrists do while there and the nature of their contact with patients. Often they are squeezed into rapid-fire drug dispensing roles. Other times they or their signatures are used to "back up" the activities of other mental health professionals. Frequently they must interrupt what they are doing to handle emergencies that arise. Although the number of psychiatrists per center remains low, the number of other mental health workers for whom they are providing "backup" has skyrocketed. Because of budgetary considerations, the educational training and professional standards of these workers can be expected to settle lower and lower, and the need for even more careful supervision should increase.

In actuality, "backup" often means providing signatures and being relegated to the position of medicator while other personnel are designated "primary therapists." However, when the patient becomes disturbed, the so-called primary therapist requests or demands that the psychiatrist quell the disturbance with drugs and then retreat into the background. These same "primary therapists" sometimes view us with contempt, seeing us as mindless pill-pushers while they are doing the therapy. Because we have been pushed into "backup" positions with medical and medication responsibility for a large number of patients, we may not have time to be more than pill-pushers. It is distressing to see psychiatrists having to sacrifice quality for quantity in institutions in which other professionals can control their caseloads to protect the quality of their practices.

This situation has led to a vicious circle: fewer psychiatrists are attracted to work in these institutions, and those who are attracted quickly "burn out" (9). In my opinion, this phenomenon is not due to lack of exposure or training during residency years but, rather, to the type of psychiatry one is compelled to practice in many large institutions and the discrepancy between the responsibilities heaped on the psychiatrist and his or her ability to meet these responsibilities. Thus there are fewer and fewer available psychiatrists in institutions, which makes psychiatric positions even more unattractive. As funding becomes more scarce, we can expect the psychiatrist's role to be even further circumscribed and even less attractive.

The Psychiatric Education Branch of NIMH is attempting to meet this situation by targeting service to minority communities as one of the priority training areas to be funded. I predict that this strategy, however well-intended, will not work. Psychiatric residents, channeled into mental health centers by residency programs dependent on NIMH funding, will quickly learn the lessons to which I refer in this paper. Exposure to situations in which true medical responsibility is not feasible is a form of aversive conditioning.

THE TWO-TIER HEALTH DELIVERY SYSTEM

What we see in large psychiatric institutions is an example of a two-tier delivery system, with one set of practices and ethics for the wealthy and another for the poor who use institutionalized settings (5). This is nothing new; we have always had a two-tier delivery system in the United States, and in a tight-money economy, the gap between the two tiers may widen. I doubt that national health plans or other third-party payment systems will raise the quality of service for institutional patients to the level available to the wealthy. Already we see the tendency to limit the mental health benefits covered by third-party payers. Third-party payment systems, however valuable, are governed by institutional rather than personal points of view.

What, then, are the options available in such a situation? For one thing, we might do nothing. As a profession we might continue on this dismal course. Such a course is fraught with some danger because as long as our practice deviates from our stated ethical principles we lay ourselves open to further litigation.

A second possibility is that we might promote such litigation in the hope of forcing the hand of the state or federal government to fund mental health. I do not think this course will be productive. Patients' rights will come squarely up against Proposition 13, and I doubt that legislators will resolve this dilemma in favor of patients' rights. On the contrary, alternate and cheaper delivery methods will be devised, often by those who have no real knowledge of the service to be delivered. We may enter an era of even further transinstitutionalization.

As a profession we might lobby very actively for adequate funding. I am sure that we are doing this already, but, for some of the reasons I have just enumerated, I am not optimistic that this will be productive.

A fourth possibility is that we might drop out of this losing game. As a profession we might urge psychiatrists not to work under the unethical conditions required in many institutions. This will certainly keep us pure and help us avoid being sued; however, society will not respond by increasing funds for mental health delivery. Society, particularly in a tight-money economy, has shown time and again that mental health is not its highest priority. Our role in institutions will be taken over by doctors of pharmacy, nurse practitioners, and physician assistants without our being given even a supervisory role that would use these personnel as physician-extenders.

A fifth possibility, which I am thinking very seriously about, is that we should change the ethics. Ethics that speak to the ideal but are impractical are counterproductive. It may be that the guidelines of our profession represent an ethic of plenty while we are in an arena of scarcity. I suggest that if we attempted to rewrite our ethical precepts in line with what is feasible in large institutional settings, we might accomplish two things. In the first place, we would drop an unwitting pretense of a standard of practice and call attention to the fact that laws for the healing arts must be revised to conform with realities. This will make us less vulnerable to lawsuits. In the second place, as we attend to the details of this rewriting we will be forced to develop an alternate method of delivery of services in institutions that will probably place more reliance on physician-extenders.

Rewriting the ethics is not so absurd as it may sound. In July 1979 the AMA House of Delegates approved for distribution a new set of ethical principles, which, I am told, is more in tune with the social and legal tenor of the times. These were to be discussed in July 1980; at the time this paper was written they were not yet official.

Although they stress our social responsibilities, the new ethics contain none of the specific prohibitions I cited above. So far as I can see, the only principle of the new code relevant to those prohibitions states that we must provide "medically competent service." This need to be on safer legal grounds is tragic testimony to the litigious society that has evolved, but these are not the guidelines I seek. I suggest guidelines that spell out the two-tier method of practice.

It might be well argued that my suggestion merely ratifies the two-tier delivery system. I would agree with that assessment, but we have in fact a two-tier system, and there is every indication that it will continue. I do not personally defend the morality of a two-tier system or a two-tier ethic, but (to borrow a phrase from commitment law) when we deal with the medically poor we may have to resort to the least immoral alternative. A high-standard ethic that cannot be adhered to and that leaves actual practice without guidelines makes less moral sense to me than a fallback position that defines reasonably well-thought-out guidelines for second-class treatment.

Comment

BY FREDERICK J. STODDARD, M.D.

I disagree with Dr. Bursten's two conclusions: 1) that the *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry* (1) should be revised to allow for the impossibility of ever giving the best care in some settings and 2) that we have no other effective means to improve psychiatric care for the poor. I agree with him that we are faced with serious ethical and clinical dilemmas. He deserves our gratitude for bringing this topic, which plagues us all, out in the open and for presenting his unusual and radical options. The evidence for my contrasting viewpoint is drawn from my clinical and peer review experience, pertinent articles, and documents that present the emerging position in psychiatry as I understand it. The following vignette helps illustrate my position:

Ms. A, a nurse, sought a child psychiatric evaluation for her 12-year-old son, Jimmy, who appeared hyperactive with questionable neurological impairment. She was referred to Dr. Z, who informed her that he did not have the time to examine the boy but referred Jimmy to a qualified social worker with whom Dr. Z worked. Dr. Z never saw Jimmy. The social worker evaluated the boy and his mother and recommended child psychotherapy and parent counseling. Ms. A refused the recommendation and refused to pay the psychiatrist when he billed her for his services. She appealed the case to a psychiatric peer review committee, which had no criteria by which to rule.

This type of supervision question has arisen often. In 1978 Blue Shield of Massachusetts asked the Massachusetts Psychiatric Society to prepare guidelines for supervision of "physician's assistants" (2); these guidelines were passed after two other psychiatrists and I labored over them for months. They were later revoked on the advice of Dr. Alan Stone due to risks of litigation. Although no doubt the safest legal course, our revocation of responsibility in this area has left Massachusetts psychiatrists without standards of care for supervision of nonmedical therapists, which encourages confusion or misrepresentation, as might apply in the case of Jimmy, and abuse and fraud in other cases.

Many emerging trends within psychiatry converge on the responsibility of psychiatrists as physicians. In caring for our patients, to what degree can we ethically delegate—or not delegate—responsibility for psychotherapy, medications, consultations, seclusion, etc.? Where does the role of the psychiatrist begin and that of the family physician, internist, pediatrician, or surgeon end? Where does the psychiatrist's role properly end and that of the psychiatric nurse, social worker, psychologist, or other nonmedical therapist begin? How can the psychiatrist best integrate and use new psychobiological data from psychopharmacology, developmental psychology, and psychoanalysis? What legal responsibilities and risks are involved in each area? What professional standards are to be expected of all psychiatrists as physicians? Are our medical diagnostic skills particularly needed for *DSM-III*? If we delegate too much, or vaguely, how does that affect our patients' care and weaken our position with third parties and with the drafters of national health insurance legislation? If we do not become more skilled in administration and delegation of responsibility, are we not leaving the mental health administration of health care systems to nonphysicians? These are a few of the wider issues that pertain to the responsibility of psychiatrists, in addition to the limited but major problem in institutions.

In his paper Dr. Bursten concludes by suggesting an apparently sensible option that psychiatric medical ethics be revised to relieve us of unrealistic ethical, medical, and legal responsibilities. He suggests a two-tier method of practice that would require us to "rewrite our ethical precepts in line with what is feasible in large institutional settings" to make them "conform with realities," "make us less vulnerable to suits," and force us "to develop an alternate method of delivery of services . . . that will probably place more reliance on physician-extenders." This view is opposed to the existing *Principles* (1), to established professional standards of care, and to new guidelines being written by APA. Although rewriting our medical ethics might relieve us of onerous responsibilities, it seems to me that it could be devastating to psychiatry and to our patients at a time when there is promise for improved quality and standards of care in all settings. Rather than retreating from medical responsibilities or rewriting our ethics, I think a better option is for us to understand and adhere to them more clearly than before, whether in private practice, academic institutions, or federal or state mental health systems.

The assertion that we must restrict our medical responsibility is heard from many quarters. Other mental health professionals and even other physicians voice such views. There are increasing demands for certification and for extensive documentation that psychiatric and other medical services meet certain standards within certain cost limits. These demands come from our own professional associations, Professional Standards Review Organizations (PSROs), governmental agencies, third parties, and the legislative and judicial systems. We must renew our licenses annually both to practice and to prescribe, be certified by the American Board of Psychiatry and Neurology, earn certificates in continuing education for licensure and Association membership, and have our fees and services reviewed by peers, the public, and third parties. The fact of "absolute confidentiality" is extinct except for those patients who pay cash for their own outpatient care. What procedures we perform and how and for what fee are now influenced by executives, legislators, judges, and even the Federal Trade Commission (3). Under such regulations, it is hardly surprising that many physicians have sought less medical responsibility—either to acknowledge new realities or in reaction to lawsuits.

However, this is not the predominant direction our profession is taking today, nor, in my view, should it be. I will cite examples in addition to the *Principles of Medical Ethics* to illustrate my sense of the direction psychiatry is taking today regarding medical responsibility.

NEW ETHICAL AND LEGAL GUIDELINES FOR PRACTICE

APA is revising its position statement on relationships with nonmedical therapists (4). At its meeting in June 1980 the Board of Trustees accepted a document titled "Guidelines for Psychiatrists in Consultative, Supervisory, or Collaborative Relationships with Nonmedical Therapists" with the additional prefatory statement that the guidelines were not an official policy of APA but "a living document to be adapted to local custom and practice." These guidelines merit a place in this dialogue and are the most current statement on this important topic. They represent the results of extensive work by the Washington Psychiatric Society, the late Dr. Warren Williams, and many others. They are specific about the relationship referred to in Dr. Bursten's paper, supervisory relationships between a psychiatrist and a nonmedical therapist:

> In a supervisory relationship the psychiatrist retains direct responsibility for patient care and provides professional direction and active guidance to the therapist. In this relationship the nonmedical therapist may be an employee of an organized health care setting or of the psychiatrist. The psychiatrist is clinically responsible for the initial workup, diagnosis, and prescription of a treatment plan, as well as assuring that adequate and timely attention is paid to the patient's physical status and that such information is integrated into the overall evaluation, diagnosis, and planning. The psychiatrist remains ethically and medically responsible for the patient's care as long as the treatment continues under supervision. The patient should be fully informed of the existence and the nature of any changes in the supervisory relationship.

The APA guidelines are especially clear about the psychiatrist's ethical responsibility under the heading "Appropriateness of Care":

> It is unethical for the psychiatrist to continue an administrative supervisory, consultative, or collaborative relationship if it is ascertained that his or her role is being misrepresented, or when convinced that the care being provided is either inappropriate or inadequate. An exception may be made when the psychiatrist is specifically accepting a responsibility with the goal of improving the quality of care so that it does become adequate. The psychiatrist with an ongoing administrative supervisory, consultative, or collaborative relationship should undertake such relationships with a therapist only if he or she is able to keep himself/herself appropriately informed of the nature of treatment and the progress of those patients about whom he/she is supervising, consulting, or collaborating, and can assure himself/herself that the treatment provided is being carried out competently and adequately.

Although these are general guidelines for the psychiatrist's use rather than ironclad rules for ferreting out fraud and abuse, they represent progress within the profession. They are consistent with other steps being taken in defining psychiatry's role in the 1980s, and some psychiatrists advocate even clearer guidelines, including such details as how many nonmedical therapists one psychiatrist can supervise and improved documentation by psychiatrists in the records of all patients for whom nonmedical therapists are participating in care. It is noteworthy that no mention of the credentials of the nonmedical therapists is made—this is due to risks of litigation for restraint of trade, but it also makes it more difficult for psychiatrists advising hospitals, third parties, and agencies to make recommendations regarding standards of care.

Two relatively recent court cases are also illustrative of psychiatry's position. The first is the *Virginia Academy of Clinical Psychologists v. Blue Cross of Virginia and Blue Shield of Virginia* (5). APA's amicus curiae testimony, given by then President-Elect Dr. Donald Langsley, clearly defined his conception of the medical training and responsibilities of psychiatrists for medical treatment of nervous and mental disorders as distinct from nonmedical therapists:

> Langsley: I might refer a patient to a psychologist for psychological therapy or psychotherapy once a diagnosis has been made and a treatment plan devised.

Question: Would you continue to supervise a clinical psychologist in the treatment of one of your patients?

Langsley: I would continue to consult with the psychologist. Forgive me if I use the euphemism of consultation. I think it is often more acceptable. But in essence, I could continue to feel that I was taking ongoing medical responsibility and that the psychologist would be taking responsibility for doing the psychotherapy in that kind of situation. Though he and I might confer regularly and periodically, I personally would want to see the patient face to face to assure myself that there was no change in the condition of the patient. In some cases I might work with the psychologist. I would see the patient regularly for chemotherapy while the psychologist was doing individual or group or family therapy.

Question: Is it in the best interests of a patient who has exhibited a nervous or mental symptom to be examined by a physician before commencing psychotherapy?

Langsley: In my opinion, it is. The way to guarantee the best possible evaluation and treatment of a patient with a mental disorder or with a nervous or mental symptom is to have a thorough evaluation by a psychiatrist or by a group of people with a psychiatrist as part of the team. The reason for the psychiatrist's involvement is first of all, to be sure that any physical disease or related physical disorder is diagnosed, and, also, to be able to make a plan of treatment which would provide the best possible treatment of the patient. That might include psychotherapy, but it might also include medication, physical treatment such as electroshock therapy in a small number of cases, and also might include hospitalization if indicated. In addition, in my opinion, the best type of treatment requires having the psychiatrist available not only for the initial evaluation but for ongoing consultation if the therapist is a nonmedical person. There is a much broader scope of treatment psychiatrists can give in the field of nervous and mental disorders than is permitted by psychologists, clinical or otherwise. The psychiatrist is a physician who is trained in all of the skills of medicine, and who in the specialty of psychiatry is trained in a number of areas that are not part of the training or skill of the clinical psychologist.

Dr. Langsley and APA supported no two-tier method of practice but, on the contrary, supported a system in which outpatient psychological services could be rendered only when these services were ordered by, supervised by, and billed through a physician. The Virginia situation represents an extreme and unusual example, but it is more consistent with psychiatry's position today.

A different situation is the *Rennie v. Klein* case in New Jersey (6), in which several physicians and the state mental health department were sued for violation of the patients' civil rights in the ways in which orders were written for forcible administration of medications by nonphysician staff. In this case psychiatry's position has been that inadequate state funding led to the inadequate conditions but that the psychiatrists were working there to improve the conditions and had the right to medicate committed patients involuntarily. Nevertheless, as Dr. Bursten suggests, one result of that type of suit has been to force psychiatrists out of state mental health systems because of legal liability, which has the effect of lowering the quality of care.

A third situation has also placed the issue of supervision of nonmedical therapists squarely in the limelight: peer review and consultation to third parties, such as the Massachusetts Blue Shield situation referred to above. There are repeated questions from various third parties as to what supervision means, especially such specifics as hours of supervision per week, the number of nonmedical therapists a psychiatrist can supervise, the credentials of those therapists, and billing practices. The answers are critical to provision of adequate and competent psychiatric treatment; yet, because of the threat of lawsuits, no answers are provided. These questions will not disappear so long as psychiatrists supervise nonmedical therapists *and* sign their names on bills for their services or supervise them in institutions. One possible option is to develop more specific guidelines for supervision. Our colleagues in such specialties as surgery, internal medicine, pediatrics, anesthesiology, and ophthalmology all have "assistants" and specific guidelines for supervision but not for a double standard of care. If we are to supervise nonmedical therapists and be requested by them to do so, shouldn't we have specific supervision guidelines as well?

TOWARD CONSISTENCY OF PRINCIPLES AND PRACTICE

Although I disagree with the means Dr. Bursten suggests, I agree on the end: improved psychiatric services for the chronically ill in institutions and for others too poor to afford them. Dr. John Talbott (7) has studied these problems in depth and has clearly and concisely described the possibile outcomes, some of which are grim. Indeed, there are no easy solutions. Community mental health is out of fashion as a federally funded priority, and it is mainly through such programs that the poor have had access to psychiatric care of good quality in the last 15 years.

I see several options for improved services, and I am cautiously optimistic about them. The first is eventual universal psychiatric coverage through flexibly designed private and public national health insurance plans. The second is continued advocacy of criteria and standards of high quality. These have been described by Nelson (8) as clinical (e.g., APA criteria sets and PSROs), practitioner (e.g., certification), program or facility (e.g., the Joint Commission on Accreditation of Hospitals), and payment (e.g. CHAMPUS, Blue Cross and Blue Shield, and Medicaid) standards.

A third option is advocacy on behalf of our patients through the judiciary for funding of appropriate serv-

ies. A fourth is limited efforts in Congress to extend services for those most in need, such as children and the elderly. Finally, we have the option of continued careful work within the federal and state bureaucracies for improved standards for the wide range of federally funded programs (e.g., military, NIMH, Medicare, Medicaid, Federal Employees' Health Benefits Program, CHAMPUS, and maternal and child health programs). It appears to me that we have more, not fewer options for improving treatment for our patients than we have had in the past. The result of our efforts may well be a downgrading of quality of care in our excellent treatment settings due to intrusions into patient care from without but an upgrading of care in our poorest treatment settings due to advocacy and oversight from within and without.

In conclusion, I find Dr. Bursten's examples and deep concerns about inappropriate delegation of responsibility down-to-earth and forthright. However, the direction toward which I feel such sound observations should lead is not an endorsement of a double standard of care but positive steps toward one equitable standard.

EDITORIAL

Are Books and Readers Facing Extinction?

> For books are not absolutely dead things, but do contain a potency of life in them to be as active as that soul was whose progeny they are. . . .
>
> Where there is much desire to learn, there of necessity will be much arguing, much writing, many opinions; for opinion in good men is but knowledge in the making.
>
> —John Milton
> *Areopagitica*

Pessimistic Cassandras have been warning for years that the art of reading books may be dying. The Common Reader of 50 years ago may be becoming as rare as the dodo, malnourished by a diet of intellectual fast food in the form of TV programs and glossy magazine articles, his taste and discrimination atrophied through contact with the emptiness of popular culture, made mentally sterile by the flood of polluted prose dumped in his environment, depressed and confused when intellectual effort is required and instant gratification must be delayed, wheezing misspelled clichés as his farewell benediction.

A readership survey conducted recently confirms this concern: the book reviews were the least read regular section of the *Journal*. Of course, low interest in the book section may indicate that the respondents were more interested in reading books outside the field of psychiatry and were doing so. But it may also reflect a feeling that books in general are not very important.

Although psychiatrists have generally prided themselves on being among the most literate and intellectual of the medical specialists, the pressures to turn our attention away from books are strong. As psychiatry becomes progressively more scientific, books may seem to convey less important or significant information than articles in journals. Books take longer to write and produce, and they therefore necessarily embody knowledge that accumulates more slowly and is less timely. Books cannot be used to communicate recent scientific advances because of this lag time. The clinician or researcher who wants to stay in touch with these advances can usually learn of them only through reading articles, attending meetings, or discussing them with his or her colleagues.

So why read books? Has the scientific emphasis in psychiatry made books outdated? The answer must be a categorical no. Books will continue to have many values and purposes in psychiatry and other scientific disciplines. Books are a large, rich, and varied medium for communication and expression. Textbooks and surveys are used to summarize composite knowledge. Books can present larger masses of data than can a single article and are used to report the results of large research projects. Sometimes the medium of the book is used to present many facets of a single problem in the case of the multi-authored monograph. Perhaps most important of all, books are used to present ideas or theories on a large scale. To ignore books is to limit one's perceptions to the microcosm and to miss the existence of the macrocosm.

This issue of the *Journal* begins some changes that we hope will highlight the importance of books and draw our readers' attention to them again. The book review section has been renamed *Book Forum* to emphasize the importance of books as a means for expressing and debating ideas. We hope to make it truly a forum, a place where there is much arguing and many opinions, a place to which readers will wander to find new ideas discussed. We will try to include both books and reviewers that reflect a diversity of points of view.

The new *Book Forum* will also include some changes in the types of books reviewed. The old staples such as textbooks and scientific monographs will of course continue to be covered. Sometimes these will be reviewed at length, and at other times briefly, depending on the complexity of their contents, the breadth of their appeal, their size and potential impact on the field, and their overall quality and merit. A new heading, Brief Mention, will be used for shorter reviews to call the readers' attention to worthwhile books that may not require a detailed review. From time to time, we will also try to have reviews of books that represent less standard intellectual fare and will appeal to epicurean tastes. We will reach into such fields as intellectual history or art or literature and try to identify exciting new books of interest to psychiatrists that they might otherwise miss. Carl Schorske's *Fin de Siècle Vienna,* reviewed in this issue, is an example of such a book. Sometimes we will also review books written about issues related to psychiatry but directed to more general readers, in order to explore how our field is perceived and described in popular culture.

Books are the major repository of our civilization's ideas. Psychiatry has by tradition been a profession "of the book," devoted to examining these and other artifacts produced by the object of its science, the human mind. As psychiatry's methods become more quantitative and objective, psychiatrists may feel tempted to ignore the larger and perhaps more blurry view of the mind conveyed by books and to value only a microscopic, precise, detailed, and factual view. As it struggles to become more scientific, psychiatry should not permit its ties to a tradition of learning and culture to become extinct. Even the microscope gains its power by enlarging what we see, not by reducing it.

NANCY C. ANDREASEN, M.D.

Dr. Andreasen is Associate Professor of Psychiatry, University of Iowa College of Medicine, Iowa City.

BRIEF COMMUNICATIONS

Use of a Self-Report Symptom Scale to Detect Depression in a Community Sample

BY JEROME K. MYERS, PH.D., AND MYRNA M. WEISSMAN, PH.D.

The authors gave the CES-D, a self-report depression symptom scale, to 515 people drawn from a longitudinal community survey. The subjects were also interviewed using the Schedule for Affective Disorders and Schizophrenia (SADS). From the information collected on the SADS, the subjects were given diagnoses based on Research Diagnostic Criteria. The results indicate a modest relationship between self-reported symptoms of depression and the diagnosis of a major or minor depression. However, the groups defined as "cases" by such reports also include many people with other diagnoses or with no diagnoses at all. Thus, symptom scales are useful for the screening of depressed persons in research studies but are only rough indicators of clinical depression in the community.

In recent years self-administered questionnaires have been used with increasing frequency to determine the incidence and severity of depressive symptoms in the community (1–11). Self-reports are economical, do not require extensive rater training, and avoid the problem of observer bias. However, the relationship between self-report symptom scales and psychiatric diagnosis is unclear, and it is uncertain how useful self-report depression symptom scales are as screening instruments for depression.

Most symptom scales treat psychiatric illness as a unitary phenomenon of varying severity without distinguishing among discrete syndromes. This concept differs from that of the clinical diagnosis, in which symptoms are not necessarily linear and additive but are instead classified into dimensions or categorical groups. This difference holds whether the symptom scale measures all psychiatric illness or a particular set of symptoms, such as depression.

Differences in determining what constitutes a case have led to a gap between epidemiologic and clinic studies. Research based on a diagnostic approach has relied heavily on patient populations and ignored community populations. Community studies have used quantitative measures, usually self-report scales, and have reported severity of symptoms but not diagnosed illness. Consequently, little is known about the relationship betwen symptom scale ratings and clinical diagnosis in community populations.

A major reason for this lack of information has been the unavailability of diagnostic instruments suitable for large-scale community studies. However, techniques to improve the reliability and validity of psychiatric diagnoses have now been developed and applied to community populations. This permits comparisons of the results of diagnostic evaluation and symptom scale rating within a community. The present paper presents data on such a comparison for depression in a community study in New Haven, Conn.

METHOD

Rating and Diagnostic Procedures

The CES-D. In 1971 the Center for Epidemiologic Studies (CES), National Institute of Mental Health, began a series of studies to develop techniques for the continuous measurement of psychiatric impairment, particularly depressive symptomatology, in the community (1). As part of this research, a 20-item self-report rating scale, the CES-D, was developed to measure depressive mood (2, 7). All items were selected from previously developed scales to represent major symptoms in the clinical syndrome of depression, as identified by clinical judgment, frequency of use in other questionnaires for depression, and factor analytic studies (12). Major contributors to the CES-D scale were selected from the Minnesota Multiphasic Inventory (13) and from depression scales developed by Zung (14), Beck and associates (15), Raskin and associates (16), and Gardner (unpublished). Scores on the CES-D were found to have a correlation of .90 with scores on the Zung scale and .81 with those on the Beck scale in a study of recovered depressed patients (17).

The SADS-RDC. A technique for making psychiatric diagnoses in a community as well as a patient population has been developed by Spitzer and associates (18) as part of a collaborative project in the psychobiology of the depressive disorders sponsored by the Clinical Research Branch, National Institute of Mental Health. Their techniques attempt to correct for unreliability due to criterion variance (the most serious problem in such research) as well as to correct for unreliability due to subject, occasion, and information variance.

Criterion variance is handled by the use of Research Diagnostic Criteria (19) to establish formal diagnostic definitions. Subject, occasion, and information variance have been approached by the development of a structured interview guide and accompanying inventory of rating scales and specific items, the Schedule for Affective Disorders and Schizophrenia (SADS) (20). This instrument is used to record data on the subject's functioning and manifest symptomatology and contains all the information necessary for making the RDC diagnosis.

Diagnostic assessment. There are several versions of the SADS based on the time period assessed—current, past five years, or lifetime. We used the lifetime version, which also includes an assessment of the subject's current status.

Based on the information collected on the SADS, the subjects were classified by the RDC. Raters underwent a three-month period of training on the SADS and RDC, and interrater reliability following training was excellent. (Information on training, reliability, and agreement with clinical records has appeared in detail elsewhere [21].)

TABLE 1
Relationship Between RDC Diagnosis of a Community Sample of 482 Individuals and Their Rating on the CES-D[a]

	CES-D Rating			
	Depressed		Not Depressed	
RDC Diagnosis	N	%	N	%
Depressed (N=22)	14	63.6	8	36.4
Not depressed (N=460)	28	6.1	432	93.9

[a]Data were missing for 33 individuals.

Subjects

The sample consisted of 515 respondents interviewed in 1975–1976 as part of a longitudinal survey begun in 1967 of a community mental health center catchment area in New Haven, Conn. (22, 23). The area has a population of approximately 72,000, which includes a changing inner-city section of 22,000 and a more stable industrial town of 50,000. It represents an ethnic, racial, and socioeconomic cross-section of the community's population.

The original sample consisted of 938 adults 18 years of age or over chosen at random from a systematic sample of 1,095 households. This number dropped to 720 in the second wave of interviews in 1969 and to 515 in 1975–1976 because of death, refusal to participate, and movement out of the area. Full methodologic details have been described elsewhere (21).

RESULTS

The CES-D and Major Depression

Table 1 shows relationships between scores on the CES-D and a diagnosis of major depression based on the SADS-RDC. Use of the traditional CES-D cut-off point of 16 and above as defining a case led to a false positive rate of 6.1% and a false negative rate of 36.4% (see table 1). Recently, Husaini and associates suggested that cut-offs of 17 and 23 provide better estimates of "possible" and "probable" cases (24). The cut-off of 17 for a probable case produced a very similar false positive rate of 5.6% and the same false negative rate (36.4%). The cut-off point of 21 (a definite case) produced corresponding rates of 4.1% and 45.5%.

The CES-D and Minor Depression and Depressive Personality

The false positive rate for current minor depression of 8% at the 16-point CES-D cut-off was similar to that for major depression. However, the false negative rate, 77%, was twice as high. For depressive personality, the false positive rate was 7% and the false negative, 57%.

TABLE 2
Distribution of Current RDC Diagnosis of a Community Sample of 482 Individuals by Their CES-D Rating

	CES-D Rating			
	Depressed (N=42)[a]		Not Depressed (N=440)[a]	
Current RDC Diagnosis	N	%[b]	N	%
Major depression	14	33	8	2
Minor depression	3	7	10	2
Depressive personality	3	7	11	3
Bipolar disease	0	—	1	—
Schizophrenia	0	—	0	—
Anxiety	4	10	7	1
Briquet's syndrome	1	2	1	—
Alcohol or drug abuse	1	2	9	2
Phobia or panic	1	2	4	1
Personality disorder	1	2		
Other	0	—	4	1
No diagnosis (not currently ill)	14	33	385	88

[a]N here refers to subjects. For subjects who had more than one current diagnosis (N=22) depression was counted if it was one of the diagnoses. If one of the multiple diagnoses was not depression the most severe diagnosis was counted.
[b]Percentages do not add up to 100 because of rounding error.

Persistent Symptoms and Major Depression

Craig and Van Natta (25), who also used CES-D, have suggested that the persistence of symptoms may be more important than their prevalence for screening devices. They suggested that a scale based only on persistence of symptoms for 5 to 7 days before interview was the most efficient way to identify individuals at high risk for the depressive syndrome, while minimizing the likelihood of contamination by individuals reporting a large number of transient symptoms.

We examined our data by determining whether one or more symptoms occurred for 5 to 7 days. The false positive rate of 16.3% and false negative rate of 31.8% we found were very similar to those obtained when the 2-week prevalence rates were used for the CES-D total score.

Diagnosis of False Positive and False Negative Cases

Table 2 shows the distribution of diagnoses on the RDC by the respondent's CES-D status (where scores of 6 and above indicate a case). Although depression was the most frequent RDC diagnosis for subjects with high CES-D scores, 18% of such respondents had other diagnoses and 33% had no psychiatric diagnosis.

DISCUSSION

The results of this study demonstrate that a self-report symptom scale can be used as a screening device to identify cases of major depression for research purposes. For example, only 6% of the cases not diagnosed as major depression by RDC were so classified by the CES-D (false positives). However, the instruments examined are not efficient in identifying cases of minor depression or depressive personality in the community.

These instruments are far less effective for clinical purposes; about one-third of the cases of RDC-diagnosed major depression were missed by the symptom scales (false negatives). If we change the cut-off point so that the false negative rate declines significantly, the false positive rate increases substantially. Consequently, a large percentage of the population identified in this way would not actually be "cases." If screening scales are to be used in clinical settings such as primary care or medical clinics to detect persons who may require treatment for depression, much lower cut-off scores would be required to reduce the false negative rate. For example, a cut-off score of 5 would give a false negative rate of 0 for major depression. However, there would then be a 30% false positive rate.

It is clear that self-report screening scales can identify many persons with a diagnosis of depression in the community. However, the group defined as "cases" by such instruments also includes many people with other diagnoses or with no diagnoses at all. Thus the screening devices are rough indicators of clinical depression in the community, but diagnostic instruments should be used if one is interested in determining the rates of diagnosed illness. Nonetheless, these instruments are extremely useful for screening depressed persons in research studies.

A Comparison of Unipolar and Bipolar Depressive Illness

BY RICHARD ABRAMS, M.D., AND MICHAEL ALAN TAYLOR, M.D.

In a study of 40 consecutively hospitalized patients with research diagnoses of endogenous depression, the authors found no difference between unipolar and bipolar depressive patients in the risk for affective disorder in first-degree relatives, proportion of EEG or neuropsychological abnormalities, clinical evidence of the depressive syndrome, or response to doctor's choice of treatment. Bipolar patients had an earlier age of onset and displayed more manic symptoms than did unipolar patients. The authors conclude that the two forms of depressive illness are clinically and genetically homogeneous, are without identifying EEG or cognitive differences, and have an equally good response to somatic treatments.

In an earlier study (1) of unipolar and bipolar endogenous depressed patients referred for ECT, we found no differences between diagnostic groups in the severity of illness, clinical psychopathology of the depressive syndrome, or response to ECT. The group of bipolar patients had onset of illness at an earlier age, a larger number of women, a greater incidence of cyclothymia and endomorphy, and a greater genetic loading for affective illness (but not for alcoholism and sociopathy). We concluded that although our data were consistent with the concept that unipolar and bipolar depressive illnesses were separate biological entities, they were a homogeneous depressive syndrome and had a uniform response to ECT.

The present study again compares unipolar and bipolar depressive patients, but the current sample was drawn from consecutively admitted patients and was studied on a much larger range of variables.

METHOD

The present study was done on an acute treatment, university psychiatric inpatient unit serving a suburban-rural population in New York state. All consecutively admitted patients were included for the 22 months ending May 1976. Each patient was interviewed by one or the other of us with a psychiatric resident who was specifically trained in principles of phenomenology and data collection and who followed

a semistructured outline to collect the necessary clinical and demographic data. At the time of the patient's discharge, a summary was prepared that included all information and that was meticulously reviewed to ensure accuracy and completeness of data.

After all data collection was completed, research diagnoses were made by one of us (R.A.), who was given the patient's chief complaint, history of present illness, and mental status portions of the research records and who was blind to all identifying information and all demographic, family history, and treatment response data.

The criteria for endogenous depression (1 through 3 required) were 1) sad, anxious, or dysphoric mood; 2) three of the following: early morning waking, diurnal mood swing (worse in the morning), weight loss of more than 2.3 kg in three weeks, retardation or agitation, suicidal thoughts and/or behavior, and feelings of guilt, hopelessness, or worthlessness; and 3) no diagnosable coarse brain disease, no use of steroids or reserpine in the past month, and no medical illness known to cause depressive symptoms.

The severity of the patient's illness on admission and at discharge was determined separately in the same manner as the diagnoses, using a scale with half-step increments in severity ranging from "not ill" (rating of 0) to "most severely ill" (rating of 4).

Family Illness

We obtained complete family history information from each proband and at least one first-degree relative (if available). If these two sources agreed that the family history was entirely negative for mental illness, no further interviews were generally obtained. If either source indicated the presence of an ill relative, an attempt was made to interview all available first-degree relatives, who were defined as those living in the United States and available for personal or telephone interview. All interviews were conducted by a research fellow without knowledge of the proband's research diagnosis. The semistructured form that was used included assessment of present and past psychopathology.

We collated the family interview protocols and all family history and interview data from the research summary, removed all identifying information, and then presented these data to a "blind" examiner who made research diagnoses in the first-degree family members. Diagnostic criteria for present psychopathology were the same as for proband diagnoses.

Diagnostic criteria for past depressive illness in relatives (1 through 4 required) were 1) an illness of at least two weeks' duration; 2) sad, anxious, or dysphoric mood; 3) at least one of the following for probable diagnosis and two for definite diagnosis: insomnia, anorexia, weight loss of more than 2.3 kg, feelings of hopelessness, feelings of guilt and/or self-blame, suicidal ideas (consummated suicide plus items 1, 2, and 4 were considered definite evidence of depressive illness), loss of interest in daily activities, and feeling slowed down; and 4) treatment by a physician with medication or ECT, with much improvement or recovery afterward.

TABLE 1
Clinical, Demographic, and Laboratory Variables for Unipolar and Bipolar Depressed Patients

Variable	Unipolar Patients (N=26)	Bipolar Patients (N=14)
Index age (years)	42.5	37.3
Onset age (years)[a]	34.0	25.4
Sex		
Male	2	4
Female	24	10
Race		
White	24	13
Black	2	1
Percent with abnormal EEG	16.7	7.7
Percent with abnormal rating on aphasia screening test	46.2	33.3
Severity of illness at admission	2.6	2.8
Duration of present illness (months)[b]	2.9	1.0
Duration of index admission (days)	48.7	30.3
Percent improved at discharge	88.3	88.1
Depression score	5.8	5.2
Mania score[c]	0.0	0.43
Catatonia score	0.34	0.43

[a]The difference between the two groups was significant ($\chi^2=3.34$, $p=.002$).
[b]$\chi^2=2.19$, $p=.035$.
[c]$\chi^2=2.48$, $p=.028$.

Diagnostic criteria for past manic illness in relatives (1 through 4 required) were 1) an illness of at least two weeks' duration; 2) euphoric, expansive, labile, or irritable mood; 3) at least one of the following for probable diagnosis and two for definite diagnosis: excitement and/or overactivity, overtalkativeness and/or rapid speech, excessive spending, excessive optimism, overestimation of own capacities, and racing thoughts; and 4) treatment by a physician with medication or ECT, with much improvement or recovery afterward.

The criteria for antisocial personality and alcoholism were those of Feighner and associates (2). For the present study, definite and probable diagnoses in relatives were combined for analysis.

Laboratory Studies

EEGs were routinely obtained for all cooperative patients and read by a "blind" examiner (R.A.) who classified them as normal, borderline, or abnormal according to the criteria of Gibbs and Gibbs (3). The aphasia screening test, a neuropsychological test of cortical dysfunction (4), also was routinely administered and read by a "blind" examiner (M.A.T.) who interpreted the results according to Heimburger and Reitan (4) and the principles of Luria (5). We have reported the detailed methodology of these procedures elsewhere (6).

TABLE 2
Patterns of Illness in First-Degree Relatives of Unipolar and Bipolar Depressed Patients[a]

Illness	First-Degree Relatives of Unipolar Patients			First-Degree Relatives of Bipolar Patients		
	Number Ill	Number at Risk	Morbidity Risk (%)	Number Ill	Number at Risk	Morbidity Risk (%)
Affective illness	13	106.5	12.21	7	47	14.89
Unipolar	8	106.5	7.51	3	47	6.38
Bipolar	5	106.5	4.69	4	47	8.51
Alcoholism	17	106.5	15.96	7	47	14.89
Antisocial personality	2	177.5	1.13	3	82.5	3.64

[a]None of the differences between the two groups was significant.

We defined unipolar depressive illness as the presence of at least one depressive episode in the absence of any history of mania or hypomania, and bipolar depressive illness as the presence of at least one manic or hypomanic episode.

Assessment of Clinical Variables

A total of 40 individual clinical signs and symptoms were coded as present (1) or absent (0); from these, three clinical scores were computed for each patient as follows:

1. Depression score (range, 0–9): the sum of depressed mood, retardation, guilt, insomnia, suicidal ideation, hopelessness, weight loss, diurnal variation, and depressive delusions.
2. Mania score (range, 0–6): the sum of hyperactivity, rapid or pressured speech, euphoria, grandiosity, intrusiveness, and flight of ideas.
3. Catatonia score (range, 0–8): the sum of mutism, stupor, negativism, posturing, catalepsy, mannerisms, echolalia or echopraxia, and automatic cooperation.

Statistical Analysis of Data

Differences between means were analyzed by independent t tests, correlations by the Pearson product-moment correlation coefficient (r), and contingency tables by raw chi-square or Fisher's exact probability test where appropriate. To test the relationship between individual clinical signs and symptoms (scored as 0 or 1) and the depressive diagnostic group (scored as 0 or 1 for unipolar or bipolar), we used the phi coefficient, a form of the product-moment correlation coefficient.

RESULTS

Of the 465 patients admitted during the study period, 40 satisfied our research criteria for endogenous depression; 26 were unipolar and 14 bipolar. Table 1 displays a variety of demographic, clinical, and laboratory variables for the two diagnostic groups. Bipolar patients were significantly younger than unipolar patients at the time of their first illness episode, had a shorter duration of their present illness just before the index admission, and had a significantly higher mania score than unipolar patients.

We examined the correlations between 26 individual clinical features and polarity of illness. Consistent with a higher mania score, bipolarity was significantly correlated with agitation and aggression (phi=.272, p=.045) and euphoria (phi=.311, p=.027) and tended to be correlated with intrusiveness, hyperactivity, rapid or pressured speech, and grandiosity ($p<.10$). Unipolar patients lost more weight than bipolar patients (phi=.340, p=.017) and tended to be more depressed ($p<.10$).

We compared the two groups on number of total hospitalizations; episodes of illness per year; and history of drug abuse, alcohol abuse, childhood hyperactivity, seizures, head trauma with unconsciousness, unexplained high fever, gestational or perinatal complications, delayed landmarks, and serious medical illness. There were no significant differences between the unipolar and bipolar patients on any of these variables.

Treatments administered to the two groups were doctor's choice and included ECT (alone or with drugs), antidepressants, lithium alone, neuroleptics alone, or lithium plus neuroleptics. The groups differed significantly in treatments received ($\chi^2=11.1$, df=5, p=.049) due primarily to the fact that more bipolar patients were treated with lithium alone (p=.01, Fisher exact probability test). The response to the various treatments did not differ for the two groups; with specific regard to ECT, the degree of improvement was 94.7% and 95.8% for the unipolar and bipolar patients, respectively.

Table 2 displays patterns of family illness of affective disorder, alcoholism, and antisocial personality for the two groups; there were no significant intergroup differences in the risk for any of the diagnoses.

DISCUSSION

We confirmed our prior finding (1) of an earlier age at onset for bipolar patients as well as a homogeneous

clinical presentation and response to doctor's choice of somatic treatments for the two groups. However, in the present study, we found no difference between groups for the risk for affective disorder in first-degree relatives. The proportion (simple prevalence) of affective illness in the relatives of the present sample was 7.7% for bipolar patients and 6.6% for unipolar patients, figures that can be compared with our prior findings of 14% and 1%, respectively. This difference may be accounted for by the improved methodology of the present study, which employed blind diagnoses of both proband and relative, as well as blind family interviews.

The higher mania scores for bipolar patients and the fact that they received more treatment with lithium suggests that manic symptoms are at times manifest in the depressed phase of bipolar illness (it was never observed in the unipolar sample), a finding that has been noted by others (7).

The shorter duration of the present illness in bipolar patients suggests that their clinical symptoms demanded earlier medical attention, perhaps due to the mixture of manic symptoms.

Our selection of the unipolar sample on the basis of a single endogenous depressive episode might bias the data in favor of homogeneity of unipolar and bipolar depression if a significant proportion of first-episode unipolar patients ultimately developed a manic attack. However, this likelihood is quite small; in a long-term follow-up study Winokur and Morrison (8) found that fewer than 5% of depressive patients followed such a course.

The present study, with its improved methodology and more extensive selection of variables, including EEG and neuropsychological testing, showed fewer important differences between unipolar and bipolar depressive patients than did our earlier report. Moreover, the differences found in the present study may be interpreted as simply a function of severity of illness (e.g., earlier age at onset, more manic symptoms) rather than as specific biological markers.

We conclude on the basis of these new data that unipolar and bipolar depressive illnesses are clinically and genetically homogeneous, are without EEG or neuropsychological differences, and have an equally good prognosis.

Predicting Outcome of Antipsychotic Drug Treatment from Early Response

BY PHILIP R.A. MAY, M.D., THEODORE VAN PUTTEN, M.D., AND CORALEE YALE, M.S.

The authors gave 48 newly admitted schizophrenic patients an initial test dose (2.2 mg/kg) of chlorpromazine hydrochloride and additional doses at 24 and 36 hours. Clinical response was measured at 48 hours and at the end of 28 days of subsequent treatment with a fixed dose (6.6 mg/kg) of chlorpromazine. There was a consistent correlation between 48-hour change and the eventual amount of improvement by the end of drug treatment for all 10 outcome criteria. The authors conclude that change early on in drug treatment is a useful predictor of outcome.

It has been established that antipsychotic drugs generally work. We now turn to the problem of how to predict outcome for the individual patient. Although most schizophrenic patients improve if given medication, a substantial number do just as well without it and some get worse or develop adverse effects. Regrettably, controlled research on prediction of response has been meager (1), and our current state of knowledge is not impressive—in a personal communication in 1976 Hollister observed that drug treatment is unlikely to make a patient play the violin if he has never played before.

Over and above statements of the obvious, can one predict whether drug treatment is likely to help a particular person? Having failed in 7 years of painstaking research to develop methods that predict the outcome for a specific patient from pretreatment information, we concluded that we may have been trying to predict from the wrong set of variables. Our rationale that we might learn something relevant to the eventual clinical outcome by studying the patient's immediate response to the drug led to procedures for monitoring the immediate response to a test dose (2, 3). Our preliminary findings that follow are most encouraging: they indicate that measuring early clinical response may be a simple and practical aid to predicting the outcome of a course of drug treatment.

METHOD

We gave an initial test dose of chlorpromazine hydrochloride and additional doses at 24 and 36 hours to 48 newly admitted patients suffering from a functional psychosis with definite schizophrenic features but not from significant physical disease, drug addiction, or alcoholism. Clinical response was measured at 48 hours and at the end of 28 days of subsequent treatment with a controlled standardized course of drug therapy. The subjects had given informed consent in a manner approved by a human studies review committee.

As described elsewhere (4), the diagnosis was substantiated by using four different sets of diagnostic criteria for schizophrenia: the diagnostic criteria used in the National Institute of Mental Health collaborative studies (5), the Diagnostic Certainty rating scale (6), the New Haven Schizophrenia Index checklist (7), and the World Health Organization criteria for the diagnosis of schizophrenia (8). Our objective was to select patients for whom treatment with antischizophrenic antipsychotic drugs was clearly indicated, an issue that we suspect may be of greater concern to the clinician than achieving complete certainty about a diagnosis of schizophrenia. Although there is no substantive evidence that drug response is predicted better by any particular set of diagnostic criteria, whether stringent or relaxed, all 48 patients met at least two of the sets of criteria and 92% met all four.

The initial dose was 2.2 mg/kg of chlorpromazine, given as oral concentrate (100 mg/ml), diluted in approximately 22 ml of orange syrup. The same dose was repeated at 24 hours, and 4.4 mg/kg was given at 36 hours (just before bedtime). After this, a fixed daily dose (liquid form) was given once daily (between 8:30 p.m. and 9 p.m.) for 28 days, toward the lower end of

TABLE 1
Pearson Product-Moment Correlations Between Clinical Measurements of Early (48-Hour) Change and Amount of Improvement After 28 Days for Schizophrenic Patients Treated with Chlorpromazine

Measure	r
BPRS (N=31)	.669
Thought disorder	.631
Anxiety-depression	.669
Paranoia	.537
Withdrawal	.513
MACC (N=29)	.573
Mobility	.597
Affect	.558
Cooperation	.511
Communication	.507

the generally accepted therapeutic range—450 mg/day for a 67.5-kg person (6.6 mg/kg). If there had been a severe toxic reaction to the first dose, it was reduced. We chose the lower end of the therapeutic range for ethical reasons.

Clinical status was rated by the treating psychiatrist on the Brief Psychiatric Rating Scale (BPRS) (9) (total score and four factors) and by nursing staff on the MACC Behavioral Adjustment Scale (MACC) (10) (total score and four subscales). The posttreatment ratings were independent; i.e., the raters were blind to the 48-hour values.

RESULTS

There was a consistent correlation between 48-hour change and the eventual amount of improvement by the end of drug treatment for all 10 outcome criteria. The Pearson correlations ranged between .507 and .669, all statistically significant at $p<.01$ or .001 (see table 1).

These correlations indicate that the more a patient's condition is improved at 48 hours, the better the eventual outcome of treatment with a fixed dose and vice versa. Put another way, change early on in drug treatment is a useful predictor of what will eventually be. In practice, when the patient improves rapidly, all is well and is likely to stay well; e.g., all 9 patients whose BPRS thought disorder scores improved 3 scale points or more in the first 48 hours did reasonably well at outcome. When no rapid change occurs, the clinician can wait or raise the dose. If he or she chooses to wait, our data indicate that he or she should do so with reduced expectations of improvement. The clinician is likely to worry about what to do with the patient who is worse after only 48 hours of drug treatment. We would not expect much benefit from continuing the same dose; for example, none of the 5 patients who were rated worse on the BPRS thought disorder scale after 48 hours of drug treatment went on to a very good outcome. It is difficult from our data to generalize about the effect of raising the dose of patients who are worse after 48 hours. At the end of 28 days on a fixed dose, we gave 4 of 5 such patients higher doses: 1 became even worse, 2 improved, and 1 remained unchanged.

COMMENT

We conclude that when patients get worse early on in drug treatment, this should be taken as a clear warning and a definite indication that something may need to be changed. For example, the dose could be raised, although the patient's condition must be carefully monitored and the possibility for eventual benefit is slight, or another drug could be prescribed instead. It is possible that the patient might do just as well, or even better, without drug treatment. Our data contradict the widespread belief that drugs do not affect thought disorder or, alternatively, that there is necessarily a lag period before the onset of drug effect.

Although our findings are subject to the usual caveats about preliminary findings from a relatively small number of patients, the consistency and magnitude of the correlations are impressive. It is easy in clinical practice to monitor 48-hour improvement, and we, therefore, suggest that this simple prognostic indicator be given further clinical trial. The underlying principle is very simple—if you want to know what is likely to happen on drug treatment, try a test dose.

MHPG as a Predictor of Antidepressant Response to Imipramine and Maprotiline

BY ALAN H. ROSENBAUM, M.D., ALAN F. SCHATZBERG, M.D., TOSHIHIKO MARUTA, M.D., PAUL J. ORSULAK, PH.D., JONATHAN O. COLE, M.D., EDWIN L. GRAB, A.M., AND JOSEPH J. SCHILDKRAUT, M.D.

To explore the hypothesis that depressed patients with low pretreatment levels of urinary 3-methoxy-4-hydroxyphenylglycol (MHPG) respond more favorably to antidepressant drugs which act on noradrenergic neuronal systems than do patients with high MHPG levels, the authors administered 150–200 mg/day of imipramine or maprotiline to 13 depressed patients. All of the 5 patients with low pretreatment MHPG levels responded to treatment compared with 1 of the 14 patients with high MHPG levels; 4 patients dropped out of the study.

Research from a number of laboratories has indicated that pretreatment levels of urinary 3-methoxy-4-hydroxyphenylglycol (MHPG), the major metabolite of norepinephrine which originates in the brain (1–3), might aid in predicting antidepressant response to specific tricyclic antidepressant drugs. In two studies (4, 5) depressed patients with low pretreatment levels of urinary MHPG were found to respond more favorably to treatment with imipramine or desmethylimipramine than patients with higher urinary MHPG levels. In contrast, three studies (5–7) have shown that patients with high pretreatment levels of urinary MHPG responded more favorably to treatment with amitriptyline than did patients with lower MHPG levels, but this has not been clearly demonstrated in other studies (8, 9).

Basic neuropharmacological studies (10) have shown both similarities and differences between the effects of imipramine and its demethylated metabolite desmethylimipramine and those of amitriptyline and its demethylated metabolite nortriptyline on various central neurotransmitters—including norepinephrine and serotonin. This literature, which has recently been reviewed by Maas (11), suggests that imipramine produces more potent effects on noradrenergic neuronal systems than does amitriptyline.

To further explore the hypothesis that patients with low pretreatment levels of urinary MHPG will show favorable responses to antidepressant drugs which act on noradrenergic neuronal systems, in this preliminary study we examined pretreatment urinary MHPG levels as a possible predictor of response to imipramine and maprotiline, a new tetracyclic antidepressant drug that exerts potent effects on norepinephrine uptake but has little effect on serotonin uptake (12–14).

METHOD

The subjects in the study were 13 depressed patients who met the Feighner criteria (15) for primary affective disorder, unipolar type, and the Research Diagnostic Criteria (16) for major depressive disorder. All patients were free of significant medical or neurological disorders and scored at least 28 on the Hamilton Depression Rating Scale (17). The patients ranged in age from 38 to 62 years; 8 were men and 5 were women. Informed consent was obtained from all patients participating in this study.

During the pretreatment baseline period, 24-hour urine specimens were collected for measurement of MHPG, which was determined by a modification of the method of Dekirmenjian and Maas (18). Patients received no psychoactive drugs for at least 10 days before and during the collection of 24-hour urine specimens with the exception of occasional doses of oxazepam, 15–45 mg/day, which were administered to 6 of the patients for anxiety or sleeplessness. All patients

were hospitalized during the period of urine collection and received a standardized tyramine-free diet for at least 24 hours before and during the entire period in which urine was collected. We used only complete urine collections, as determined by nurses' observations and by creatinine concentration and total volume.

After the pretreatment baseline urine collections the patients were randomly assigned to double-blind treatment with maprotiline or imipramine. These drugs were initially administered at a dose of 150 mg/day, and most patients continued to receive this dose for the first two weeks of the study (although a few patients required transient decreases in dosage because of side effects). During weeks two, three, and four of the study the protocol allowed drug dosages to be increased by 50 mg every three days, and all but 1 of the 9 patients who completed the four-week protocol and who failed to respond to treatment at a dose of 150 mg/day received a therapeutic trial of 200 mg/day during this study.

The Hamilton scale scores were obtained during the pretreatment baseline period and weekly throughout the study. Patients were considered responders if the Hamilton scale score at four weeks was less than 16 and had fallen at least 60% from the baseline value. Although patients who failed to complete the four-week protocol (dropouts) were regarded as nonresponders, wherever possible data were analyzed in two ways, including these patients as nonresponders and excluding these patients from data analysis. All clinical diagnoses and Hamilton depression ratings were made by clinicians who were blind to the biochemical data, and all biochemical determinations were performed by laboratory personnel who were blind to the clinical data.

RESULTS

Pretreatment urinary MHPG levels ranged from 1370 to 3640 μg/24 hours. This range is similar to that observed in a previous series of patients (19) with unipolar endogenous depression, in which the mean MHPG level was 1950 μg/day. In the present study 6 of the 13 patients had pretreatment MHPG levels of 1950 μg/day or less, which we shall refer to as "low" levels, and 7 of the 13 patients had pretreatment MHPG levels over 1950 μg/day, which we shall refer to as "high" levels.[1] The mean age (±SE) of the low-MHPG group was 47±8 years; the mean age of the patients with high MHPG levels was 48±8 years.

In an analysis of the data in which dropouts were considered nonresponders, 5 of the 6 patients with low pretreatment MHPG levels had a favorable response to maprotiline or imipramine. In contrast, 6 of the 7 patients with high pretreatment MHPG levels did not respond to treatment with these drugs (p=.05, Fisher exact probability test). The 1 patient with high MHPG levels who was classified as a responder relapsed after 31 days of treatment even though treatment with imipramine was continued.

Excluding patients who dropped out, all of the 5 patients with low pretreatment MHPG excretion who completed the four-week protocol showed a favorable response to treatment with maprotiline or imipramine, while only 1 of the 4 patients with high pretreatment MHPG levels showed a favorable response (p=.05, Fisher exact probability test). The mean (±SE) Hamilton scale score at baseline was 32±1 for the patients with low pretreatment MHPG levels and 36±3 for the patients with high MHPG levels. At the end of the four-week study, the patients with low MHPG levels had a mean Hamilton scale score of 10±1, and the patients with high MHPG levels had a mean score of 20±4 ($p<.05$, one-tailed t test). The mean percentage of reduction in Hamilton scale scores was 69±4% for patients with low urinary MHPG levels and 45±13% for the patients with high MHPG levels ($p<.05$). The decrease in mean four-week Hamilton scores from baseline values was greater in patients with low urinary MHPG levels (22±1) than in patients with high MHPG levels (16±4), although this difference did not attain statistical significance.

DISCUSSION

In this study low pretreatment urinary MHPG levels (1950 μg/day or less) predicted a favorable response to treatment with either imipramine or maprotiline. The incidence of and reasons for dropping out also support a differential responsivity based on pretreatment urinary MHPG levels; only 1 of the 6 patients with low pretreatment urinary MHPG levels dropped out of the four-week study, and this patient dropped out because of an allergic dermatitis. In contrast, 3 of the 7 patients with high pretreatment urinary MHPG levels (above 1950 μg/day) dropped out, and all of these patients dropped out due to the occurrence of troublesome side effects (other than allergic dermatitis) in conjunction with a lack of clinical response.

Thus, our results support previous findings which suggest that patients with low urinary MHPG levels are more responsive to treatment with drugs that inhibit norepinephrine uptake than are patients with high pretreatment urinary MHPG levels. However, since no patients in this study received more than 200 mg/day of either antidepressant drug, we are unable to rule out the possibility that patients with high pretreatment levels of urinary MHPG might be responsive to more vigorous treatment. Further studies to explore this possibility are currently in progress.

[1] Of the 6 patients who received oxazepam, 3 had low pretreatment MHPG levels and 3 had high pretreatment MHPG levels.

Drug-Related Admissions to an Inpatient Psychiatric Unit

BY RONALD B. STEWART, M.S., PHILIP K. SPRINGER, M.D., AND JOHN E. ADAMS, M.D.

The authors prospectively monitored 60 consecutive admissions to an inpatient psychiatry service to determine the role of drugs in psychiatric hospitalization. They categorized drug-related problems as 1) drug intoxication, 2) drug abuse, 3) side effects of therapeutic drugs, and 4) noncompliance with prescribed medications. During the 6-month study 25 (41.7%) of the admissions were related to drug use; in 16 (26.7%) admissions a drug-related problem was identified as the primary cause of hospitalization. Alcohol was involved in 8 admissions, and Fiorinal, cocaine, and flurazepam were each related to 2 admissions.

The number and use of drugs that influence behavior have increased tremendously during the past 25 years. The availability of tricyclic antidepressants, neuroleptics, and anxiolytic drugs in the physician's armamentarium has dramatically affected the nature and course of mental illness in this country. Phenothiazines (1), for example, have been given credit for the dramatic decline in the number of hospitalized schizophrenic patients. Stolley and associates (2) documented the popularity of these agents in a study of drug use in an American community showing that 17% of all prescriptions were for psychotherapeutic drugs.

Advances in research on and the development of psychoactive drugs have not been without liabilities since no drug is completely safe, particularly if used improperly. The same drugs that have reduced the number of hospitalized schizophrenic patients have been associated with major side effects, including tardive dyskinesia (3). Problems related to the abuse of psychoactive drugs have in some cases reached epidemic proportions; they are perhaps most obvious in psychiatric patients, in whom alcoholism, drug overdose, and extrapyramidal side effects occur frequently.

Recently, an enhanced awareness of drug-induced illness has led to systematic investigation of this problem. Studies of hospitalized medical patients have shown that 1.7%–4.5% of admissions are due to drug-induced disease (4–8). McKenny and Harrison (9) expanded the definition of drug-induced disease to include all drug-related problems and found that 27.3% of medical patients had a drug-related problem on admission. To our knowledge similar studies of psychiatric patients have not been conducted. We conducted a prospective epidemiologic study of patients admitted to an adult inpatient psychiatric unit to delineate the role of drugs in psychiatric admissions.

METHOD

The 60 patients in our study were consecutive admissions to an inpatient adult psychiatry service over a 6-month period who were primarily referred by psychiatrists.

One of us (R.B.S.) prospectively monitored patients by attending daily staff rounds, reviewing medical records, and interviewing newly admitted patients to obtain a drug history. Whenever possible, family members and/or friends of the patients were questioned concerning the patient's drug use and drug compliance habits. When indicated, a toxicology screen on blood and urine was performed to confirm the presence of drugs. Final assessment of the effect of drugs on admission was made after the patient's discharge from the hospital.

We developed the following criteria and definitions for drug-related admissions before initiation of the study:

Drug-related admission. Patient was admitted as a direct result of drug use or because drug use contributed to the need for hospitalization.

Drug intoxication. Patient intentionally took a drug overdose to attempt suicide.

Drug abuse. Hospital admission was related to the patient's abuse of a drug or drugs not being used for therapeutic purposes. We evaluated each patient by interviewing the patient and his or her relatives, by chart review, and by information obtained from the referring psychiatrist to determine if the use of drugs such as alcohol, cocaine, or propoxyphene was related

Received Oct. 25, 1979; revised March 7, 1980; accepted April 14, 1980.

to the admission. We did not use strict drug abuse criteria such as physical dependence, because a patient could be abusing drugs at the time of admission and not show evidence of true dependence. Many patients had acknowledged using drugs of abuse, but if in our opinion the drug or drugs had no direct bearing on hospital admission, we did not consider the patient as a drug abuse admission.

Side effects. Hospital admission was related to adverse effects of therapeutic agents used in normal therapeutic doses (e.g., neurotoxicity from lithium or ataxia from anticonvulsants).

Noncompliance. Hospital admission was related to the patient's not following directions for prescribed medications (e.g., a patient with manic-depressive illness refusing to self-medicate with lithium or a patient abusing a prescribed narcotic).

A structured monitoring protocol was developed to collect information concerning therapeutic and social drugs used immediately before admission and to assess the severity of detected drug problems in the patient. We categorized drug-related problems into four major groups: 1) drug intoxication (overdose), 2) drug abuse, 3) side effects of therapeutic drugs, and 4) noncompliance with prescribed medications. We also noted the drugs causing the problem and specific effects of the problem. We reviewed all patient evaluation forms at the time of discharge to assess to what degree the hospital admission was related to drug use.

RESULTS

During the 6-month period of study, there were 60 admissions to the psychiatry service, 25 (41.7%) of which were related to drug use. In 16 (26.7%) admissions we identified a drug-related problem as the primary reason for hospitalization. The average age of the 60 patients admitted to the unit was 33.9 years; 24 (40%) were men and 36 (60%) were women. The average age of the 25 patients admitted with a drug-related problem was 34.3 years; 10 (40%) were men and 15 (60%) were women.

Of the drug-related hospitalizations 13 (52%) resulted from drug abuse, 4 (6.6%) resulted from drug intoxication (suicide attempts), 3 (12%) were because of drug side effects, and 5 (20%) were related to noncompliance with prescribed medication. The largest number of drug-related admissions involved abuse of alcohol (N=8). Cocaine, flurazepam, and Fiorinal were each implicated in 2 drug-related admissions. One patient each was addicted or habituated to meperidine, propoxyphene, or butorphanol; admission of 2 patients was related to Fiorinal. Five patients were admitted with problems related to noncompliance with prescribed medications. One patient had been noncompliant with carbamazepine, which resulted in exacerbation of a seizure disorder, and 3 patients had been abusing Fiorinal, chlorpromazine, or butorphanol. One diabetic patient was admitted because she had factitiously induced numerous hypoglycemic episodes with her prescribed insulin.

COMMENT

Our study indicates that the incidence of drug-related admissions to an inpatient psychiatric unit is significantly higher than suggested in previously reported studies for medical wards (5–8). In this study we focused on a broad range of drug issues that present patient management problems for the psychiatrist. It has been estimated (10) that 16%–28% of all medical admissions in the United States are directly related to alcohol abuse. Since our data suggest that drug-related hospital admissions represent a major problem for the psychiatrist, one could question whether psychiatrists and mental health nurses are adequately prepared to deal with the nature and scope of these drug problems. It may be desirable to increase the emphasis on pharmacology, toxicology, and therapeutics in their training programs.

Most physicians feel that patients will follow their advice when medications are prescribed, although there is solid evidence to the contrary (11, 12). Because problems of noncompliance are prevalent among psychiatric patients, the psychiatrist must be especially vigilant to problems of medication misuse.

We do not know whether the fact that this study was conducted in a university teaching hospital which serves as a referral hospital and is clearly not representative of the average inpatient psychiatric unit resulted in an increased or decreased number of drug-related admissions. We believe that similar studies should be conducted in other inpatient and ambulatory care settings to more clearly define this problem.

Depression as Expressed in Pre-Columbian Mexican Art

BY JUAN-RAMON DE LA FUENTE, M.D., AND DONATO ALARCÓN-SEGOVIA, M.D.

While undertaking a larger study dealing with representations of disease in pre-Columbian ceramic figures, the authors found four figures in which depression was clearly depicted. Their findings prove that psychiatric disorders did not go unnoticed by the people who inhabited the American continent before the arrival of the Spanish.

Depression, an unwelcome companion of man for thousands of years, has been traced back to ancient Egyptian manuscripts, to the Old Testament, and to the teachings of Aristotle and Hippocrates. These documents have been described and dealt with by various authors (1–3). Conversely, there are few accounts of depression in pre-Columbian times. However, pre-Columbian sculptors were keen observers and recorders of states of mind, and we and others have previously referred to the acumen of their empiric clinical observations (references 4 and 5 and an unpublished paper by Alarcón-Segovia and de la Fuente). We therefore sought evidence of depression in pre-Columbian Mexican art. Although depression may not always have been specifically identified as such by the pre-Columbian people of Mexico, in this report we present evidence that they recognized it, attempted to prevent it, and probably had some form of treatment for it (6, 7).

METHOD

We reviewed the entire collection of the Museo Nacional de Antropología in Mexico City, including that portion in its warehouses. We also reviewed various large private collections in Mexico City and the collection of the Regional Museum of Jalapa, Veracruz. Technical support was amply provided by the Section of Archeology of the Museo Nacional de Antropología. It was not always feasible to distinguish between pathological features and stylistic traits. However, we believed that some stylistic traits afforded actual representations of disease, albeit involuntarily. From the initial survey we selected about 200 pieces, both in ceramic and in stone, for further study and to be photographed. One hundred fifty pieces were finally considered to represent pathological features or states of mind. Among these were realistic representations of cirrhosis of the liver, brain tumors, paraplegia, goiter, Pott's disease, congenital syphilis, and skin disorders.

ARCHEOLOGICAL BACKGROUND

The region of America that encompasses the southern two-thirds of Mexico and northern Central America to Nicaragua is known as Mesoamerica. It is particularly important anthropologically and archeologically because here the Indian population reached, by anyone's definition, the stage of true civilization (8). The main cultures that inhabited this geographic area were

those of central Mexico, western Mexico, Oaxaca, the Gulf coast, and the Maya civilization. In turn, these cultures can be divided into three periods: the preclassic, from 2300 B.C. to 100 B.C.; the classic, from 100 B.C. to A.D. 950; and the postclassic, from A.D. 950 to the time of the Spanish conquest in 1521 (9, 10).

FINDINGS

We found four human ceramic figures in which depression was clearly depicted. Figures in which grief or sorrow was apparent were also found but are not presented here.

Postpartum depression is well illustrated by the piece shown in figure 1. The postpartum stage is evidenced by the open vulva and hanging breasts. The former is a feature we have found only in figures representing immediate puerperium. The subject is in deep sorrow, appears greatly depressed, with a sad face, and gives the impression of extreme hopelessness. The figure belongs to the western Mexican early classic culture known as the shaft-tomb complex because the figures usually were found in deep ground burial chambers connected to the surface by shafts. These figures usually were placed in corners of the chamber or at the head of the body remains (11).

The old woman biting her fingers (figure 2) would seem to represent agitated depression (involutional melancholia). Features of this disturbance include the involutional age, psychomotor agitation, and melancholia—literally, black bile—as described by Hippocrates, who also described epilepsy, mania, and dementia (12). The old age and the biting of the hand with evident anxiety illustrate well the saying of Plutarch (A.D. 46–120), "Every little evil is magnified by the scaring spectres of his anxiety" (3, p. 67). This figure belongs to the late classic period of the Mayan culture (A.D. 600–900) and was found in 1957 on the island of Jaina off the coast of Campeche. Ceramics from this island excel in depicting naturalistic features of daily life.

The gloomy, taciturn, despondent man shown in figure 3 appears to depict the image of a retarded depression. One can reason that he is also akinetic and anhedonic. The deepness of his depression brings to mind the words of Celsus (A.D. first century): "There are forms of madness that go no further than sadness" (13). This figure also belongs to the shaft-tomb culture of western Mexico and was found in Colima, close to the Pacific coast.

Figure 4 presents another example of depression in the elderly. This figure from central Veracruz on the Gulf coast of Mexico illustrates the bland affect, the silence, the lowered glance, and the drooping lip characteristic of depression. His stare recalls Galen's description of the melancholic state: "dread and desire of death at the same time" (14).

DISCUSSION

The ceramic sculptures presented here provide evidence that the pre-Columbian inhabitants of Mesoamerica recognized the profound changes that people undergo when they are depressed. They give us insight into the fact that the unknown artists who made them were able to convey the expression of states of mind, a skill that appears late in art.

The pre-Columbian people apparently recognized dementia (15) and other psychoses (16) and, according to Vargas-Castelazo (6), who reviewed the chronicles of the Spanish missionaries of the 16th century, they distinguished two forms of depression: *tlahuiloca-yotl*, or agitated, and *xolopiyotl*, or retarded. They seem to have been particularly concerned with the prevention of "postpartum blues," since, according to Sahagún in his *Historia General de las Cosas de Nueva España* ("General History of the Matter of New Spain") (7), the midwife practiced what could be interpreted as supportive psychotherapy. She would tell the woman who had just given birth how brave and resourceful she had been, "alike the eagle and the tiger, having won an actual battle equivalent to that fought by the bravest soldiers." Sahagún's information was gathered firsthand from the Indians. Arriving only a few years after Cortés' conquest of Mexico, Sahagún trained young Indians to write Nahuatl, the language of the Aztecs, into an alphabet and had them interview the Aztec elders with prepared questionnaires. In this way he obtained direct information, which he compiled in several volumes and codices.

The herbal medicine of the Aztecs, as described also by Sahagún, had a preparation consisting of two herbs, the *iztauhyatl* and the *quauhyayual*, that was meant for one who had "anguish in the heart by reason of some bad humor that oppresses him" (17, p. 311). These herbs, said to produce good results, were boiled in water and drunk.

It is apparent, therefore, that manifestations of disease, including those of disorders of the mind, did not go unnoticed by the people who toiled in Mesoamerica long before the arrival of the Spaniards. It is possible that their concern for the recognition and management of psychiatric illness later resulted in the foundation, by the Spanish missionary Fray Bernardino de Alvarez in 1566, of the first hospital in the Americas for the study and care of mental disorders (18).

Treatment of Persons Found Incompetent to Stand Trial

BY LINDA PENDLETON, PH.D.

Persons found incompetent to stand trial comprise the largest group of psychiatric patients committed to mental hospitals through the criminal justice system in the United States. The law dictates that these patients receive short-term treatment aimed specifically at enabling them to stand trial with as little delay as possible. The author describes the treatment and assessment aspects of a program that admits approximately 200 trial-incompetent persons each year. During 1978, 90% of the 205 patients discharged from this program were certified by the treatment staff as competent to stand trial; 97.5% of that group subsequently completed the trial process.

Persons found incompetent to stand trial comprise the largest single group of criminal commitments to mental hospitals in the United States. It has been estimated that as many as 15,000 persons are committed on this basis at any one time, approximately 52% of all criminal commitments in mental hospitals (1). As a result of a 1972 Supreme Court decision (2), restoration to competency within a reasonable period is now required in order to retain a patient on an incompetency to stand trial commitment. Much has been written about incompetency but surprisingly little about its specific treatment. In this report, I describe an innovative treatment program for incompetency at Atascadero State Hospital, California's primary treatment facility for the mentally disordered criminal offender.

CHARACTERISTICS OF PATIENTS

Patients in this treatment program have all been adjudged, according to California Penal Code statutes, unable by reason of mental disorder to understand the nature of the proceedings taken against them and/or to cooperate with counsel in the preparation of a defense. Criminal charges against these patients range from misdemeanors, such as defrauding an innkeeper, to felonies, such as homicide. Thus far, all of the patients have been men, and the most common diagnosis among them has been schizophrenia, paranoid type; approximately 90% of the 205 patients who were dis-

charged from this program during the calendar year 1978 had this diagnosis. Generally patients are acutely psychotic upon admission, with delusions that are frequently related to their offense. Described below is a typical patient found incompetent to stand trial who was admitted to the treatment program at Atascadero State Hospital.

Mr. A, a 32-year-old man, was diagnosed schizophrenic, paranoid type, upon admission. He had been charged with assault with a deadly weapon after striking a man with a two-by-four board. The circumstances of the offense were as follows. Mr. A was obtaining gasoline for his vehicle at a service station when another individual, unknown to him, pulled up for gas. That individual had a CB radio in his automobile, and Mr. A reacted with some alarm because he believed CB radio owners were involved in a conspiracy to broadcast information about his sex life. Mr. A promptly grabbed the nearest available weapon, a board from an adjacent construction site, and assaulted the CB owner. Upon Mr. A's admission to the hospital he was able to coherently report the events leading up to his arrest, but he maintained that his offense was justified given his belief that a gross violation of his personal privacy had been perpetrated by owners of CB radios.

TREATMENT PROCEDURES

Upon admission to our hospital each patient's competency is assessed by a psychiatric technician specially trained in the administration of the Competency to Stand Trial Assessment Instrument (3). This instrument was developed as part of a project undertaken by a multidisciplinary team of lawyers, psychiatrists, and psychologists from the Laboratory of Community Psychiatry at the Harvard Medical School who sought to demonstrate quantifiable clinical criteria for competency to stand trial. Their purpose was to design instruments that would accurately assess competency, conceptualized and expressed, in language with sufficient familiarity to both the law and psychiatry to provide a basis for effective communication and assessment of the issue. The resulting Competency Assessment Instrument is a structured interview and rating system that yields an assessment of the accused's capabilities on 13 separate dimensions of competency to stand trial. The 13 dimensions of competency are as follows: appraisal of available legal defenses, unmanageable behavior, quality of relating to attorney, planning of legal strategy, appraisal of roles of courtroom personnel, understanding of court procedures, appreciation of charges, appreciation of range and nature of possible penalties, appraisal of likely outcome, capacity to disclose pertinent facts to attorney, capacity to realistically challenge prosecution witnesses, capacity to testify relevantly, and self-defeating versus self-serving motivation. We have used this assessment of capability, which is conducted under the supervision of the program's psychologist, to identify specific deficits in the patient's ability to cope with his legal situation.

Following the admission assessment, each patient participates in an individual admission team conference in which an interdisciplinary treatment team, comprised of psychiatric technicians, registered nurses, a social worker, rehabilitation therapist, psychologist, and psychiatrist, interviews him and formulates a treatment plan. The treatment plan is designed to eliminate or reduce those symptoms that interfere with standing trial, more commonly delusional beliefs about the alleged offense or the defense attorney. Although traditional methods of treatment are employed, including psychotropic medication and structured activities such as occupational therapy and physical recreation, we also use specialized individual and group therapy. These focus on orienting the patient to the nature of the proceedings being taken against him and on building relationship skills essential to cooperating with the defense counsel.

Once the patient's deficiencies that were identified in the admission assessment have been remedied or sufficiently reduced, he is referred by his treatment team to a competency class. General information is presented in class regarding pleas that may be entered in court, roles of courtroom personnel, courtroom procedure, and appropriate courtroom behavior. After completing the competency class, which includes a written examination on the information that was presented or an oral examination in the case of illiterate patients, the patient next participates in a videotaped mock trial.

The mock trial, developed with the assistance of judges and attorneys, is a treatment and assessment procedure whereby the patient is exposed to a simulated courtroom situation tailored to his own individual case. This is designed to provide the patient with a behavioral rehearsal with feedback, as well as to desensitize him to the stressful situation of standing trial on criminal charges. In addition, it provides an assessment of the patient's capability of withstanding the stress of a trial before he is actually referred back to the court.

ASSESSMENT PROCEDURES

Assessment of the patient's competency to stand trial involves a sequence of procedures that begin with the baseline data collected at the time of the patient's admission through interviewing him with the Competency to Stand Trial Assessment Instrument. The next assessment step, which is less formal, involves a judgment by the patient's treatment team that his problems in competency noted on the admission assessment have been adequately treated; this judgment results in his referral to the competency class. Next is the examination at the end of the class; a score of 70%

is necessary to pass. The patient's performance in the mock trial is also scored pass or fail. A failure in either the class or the mock trial results in the patient's being referred back to the treatment team for more individual work in the remaining areas in which he or she is deficient. After additional training in these areas the patient repeats the failed activity, and his performance is reassessed.

When the patient successfully demonstrates his competency in the class and the mock trial, he is referred to the disposition staff interview, the final assessment procedure. The Program Director, or his assistant, conducts a formal interview with input from the interdisciplinary treatment team. The interview consists of an amalgam of prior assessment procedures, including an abbreviated version of the Competency to Stand Trial Assessment Instrument and questions on information covered in class, with particular attention paid to areas in which the patient demonstrated deficiencies earlier in the assessment sequence. In addition, a modified mental status examination is conducted to check for the presence of symptoms formerly identified as interfering with the patient's competency to stand trial. If the patient successfully completes this procedure, he is referred back to the courts as competent to stand trial; if the patient fails, which is rare at this stage, he is referred back to the treatment team for additional treatment in deficient areas.

RESULTS

The effectiveness of this treatment program is best demonstrated by the fact that, in 1978, 97.5% of those patients certified competent by the program staff were able to successfully complete the trial process upon their return to court. During 1978, 184 patients (90%) of the 205 patients discharged were certified competent. The remaining 10% of the patients either failed to attain competency within the time limits specified by state law (patients must achieve competency within 3 years or the maximum time they could have served if convicted of the offense, whichever is less) or they made so little progress that they were deemed unlikely to attain competency. During the 15 months preceding April 1979, the average duration of treatment before competency certification was given was 104 days.

It is our hope that eventually controlled studies may be undertaken to determine the relative impact of various facets of our treatment program.

Interpersonal Factors in the Psychiatry Clerkship: New Findings

BY CAROLE S. ORLEANS, PH.D., JEFFREY L. HOUPT, M.D., AND DAVID B. LARSON, M.D.

The authors took an empirical approach to determining ingredients of a successful psychiatry clerkship. They collected measures of clinical, didactic, and interpersonal experiences throughout the clerkship and correlated these with a range of outcomes. Correlations showed that positive relationships with supervisors, fellow students, and patients were strongly related to favorable attitudes and opinions at the end of the clerkship and to improvements in self-rated clinical skills. Only outcomes related to formal knowledge were independent of these factors. These findings highlight the importance of structuring a positive interpersonal environment for the psychiatry clerkship.

Which experiences contribute most to positive outcomes in a psychiatry clerkship? The data to answer this question are currently limited to studies asking students to rank different activities and experiences according to their relative value. From these studies (1-5), one finds that high levels of patient involvement and responsibility are ranked most highly and that experiences involving positive interpersonal relationships with supervisors, peers, and patients are also frequently singled out as particularly valuable.

How well do students' rankings correspond to actual positive changes in their knowledge, skills, and attitudes? In this study we took an empirical approach to identifying ingredients of a successful clerkship. Our main objective was to determine correlates of positive outcome in four domains—knowledge, skill, attitude, and opinion. We incorporated several measures of the interpersonal aspects of clerkship training in addition to measuring a broad range of actual didactic and patient care experiences.

METHOD

Subjects. Our subjects were 92 of 110 second-year Duke medical students completing their required 8-week psychiatry clerkship during the 1977 calendar year who agreed to participate in the study. The Duke psychiatry clerkship program has been described in detail elsewhere (6).

Training measures.[1] To measure training experiences, students were asked to complete four biweekly summaries of their clerkship activities. These periodic summaries avoided reliance on a single, less accurate retrospective report. Students estimated the actual number of hours they had spent during the previous 2 weeks in 6 different modes of training (supervision, demonstration, formal instruction, study, training-related staff interaction and training-related student interactions) and in 7 different types of supervised clinical experience (evaluation, crisis intervention, pharmacotherapy, psychotherapy, family therapy, referral for further mental health care, and liaison-consulting). Students also documented various aspects of their patient care experience. We determined the number of psychiatric and nonpsychiatric patients for whom the students assumed a substantial amount of responsibility and derived a single score representing the percent of psychiatry patients. We also collected bipolar numerical ratings of severity of disorders, duration of treatment needs, degree of overall patient care responsibility, and adequacy of supervision. Mean scores based on all four biweekly summaries were calculated for each training measure and used in subsequent correlations.

Outcome measures. Attitude and perceived skill ratings were obtained before and after the clerkship, and change scores were derived by subtracting preclerkship from postclerkship scores. Seven highly correlated attitude scales described in detail elsewhere (7) were combined to yield a single score reflecting attitudes toward psychiatry, psychiatric patients, and psychiatric techniques. Students used numerical bipo-

lar rating scales to rate their level of skill in each of 9 areas: evaluation, crisis intervention, pharmacotherapy, psychotherapy, family therapy, referral, liaison-consulting, treating mild disorder, and treating severe disorder. After completing their clerkship, students rated their overall satisfaction with the clerkship using a bipolar numerical rating scale. Positive response bias was minimized by collecting attitude, skill, and satisfaction ratings in addition to the biweekly summaries, apart from usual clerkship evaluation procedures, using special coding to preserve students' anonymity.

RESULTS

Preliminary analyses showed that all pre- and postclerkship changes in attitude and perceived skill were positive and significant at the $p<.05$ level or higher.[2] Overall satisfaction ratings were also favorable; the mean rating was +6.4 on a scale ranging from −10 (extremely dissatisfying) to +10 (extremely satisfying). The mean National Board of Medical Examiners (NBME) score was 551, placing overall performance at the 68th–69th percentile.

To identify clerkship experiences associated with positive outcomes, we computed Pearson product-moment correlations between outcome and training measures. Because of the large number of correlations performed, a conservative significance level of $p<.02$ was chosen (two-tailed, df=90). Table 1 presents only the significant correlates for all outcome measures.

[2]Results of analyses not reported are available on request from Dr. Orleans.

Looking first at the correlates of attitude change, we find that table 1 suggests that interpersonal training experiences play a crucial role in shaping medical students' attitudes toward psychiatry, psychiatric patients, and techniques. Highly rated relationships with house staff (primary clerkship supervisors), senior staff, and patients as well as ratings of the quality of overall supervision correlated positively with a favorable attitude shift and with a rating of overall clerkship satisfaction. Measures of the amount of time spent in interpersonal teaching experiences (supervision, demonstration, contact with fellow students, and contact with house and senior staff), the degree of responsibility for patient care, and the quality of peer relationships during the clerkship were also correlated positively with overall satisfaction with the clerkship. Attitude change and overall satisfaction measures thus seemed to tap similar outcomes and were themselves positively correlated ($r=.48$, $df=90$, $p<.001$).

Turning next to perceived skill outcomes, table 1 shows that the amount of time students spent in a given clinical activity correlated with improvements in self-rated skill in that and related activities. Table 1 correlations also suggest that positive didactic and supportive relationships with supervisors and peers are needed to maximize benefits of high levels of patient contact and responsibility. Satisfaction with house staff relationships correlated positively with 6 of 9 skill improvements, and quality of peer interactions was associated with improvements in psychotherapy and family therapy skills and in treating severe disorder. Overall, positive clerkship relationships seemed most important for teaching complex interpersonal treatment skills and clinical responsibilities that typically generate a high level of anxiety in novice therapists (e.g., individual and group psychotherapy and treating severe disorder).

Finally, table 1 shows only one significant correlate for NBME scores—time spent in crisis intervention activities was inversely related. Surprisingly, NBME performance did not even correlate with measures of time spent studying and reading. It is possible that students prepared for these exams outside of their usual clerkship activities. Additional correlations[3] showed that NBME scores failed to correlate significantly with any of the other 11 outcome measures, indicating that the cognitive outcomes it taps are fairly independent of the perceived skill, attitudinal, and affective outcomes tapped by other measures.

COMMENT

The interpersonal context of training emerged as the single most important factor influencing clerkship outcomes. Correlations suggest that positive relationships with supervisors and fellow students during the clerkship play an extremely important role in shaping positive attitudes toward psychiatry and psychiatric patients and techniques and in determining satisfaction with training experiences. Moreover, the amount and quality of clerkship-related peer and supervisor contact was strongly related to skill improvements, particularly for the most demanding interpersonal treatment skills. Given the crucial role of interpersonal training experiences, curricula relying in large part on impersonal and self-instructional teaching aids may not have the best outcomes (8).

Future research should clarify determinants of a positive interpersonal experience during the psychiatry clerkship. Along these lines, positive relationships probably combine didactic, modeling, and supportive functions: relaying concrete knowledge and helping students manage the anxieties commonly elicited by clerkship responsibilities (9). Modeling and support functions may give house staff an especially critical role. Because students see house staff as more similar to themselves than senior staff, they may be better able to identify with house staff and to receive more helpful modeling and support. Other studies of the psychiatry clerkship (1, 3) have found that ease of identifying with supervisors contributes to positive attitude and opinion outcomes. In general, similar models are often more helpful than dissimilar expert models in teaching a new skill or in overcoming skill-related anxieties (10).

Psychiatric Residents' Attitudes Toward Teaching

BY KENNETH E. CALLEN, M.D., AND JOHN M. ROBERTS, M.D.

The authors surveyed psychiatry residents in academic training programs to determine the amount of time they spent in teaching activities and to assess their attitudes toward teaching. They found that most residents spent from 1 to 2 hours per day teaching and felt they should do more. They tended to see themselves as capable teachers, and they valued traditional medical skills. They did not seem to value the use of audiovisual materials, written handouts, or self-instructional materials. Most of the residents had received no formal instruction designed to make them better teachers or direct feedback from faculty supervisors about their teaching skills.

The teaching of psychiatry has become a popular subject at national meetings and in journal articles. Interest in this topic is clearly shown by the increasing attendance at meetings of organizations devoted to education, such as the Association for Academic Psychiatry, the American Association of Directors of Psychiatry Residency Training, and the Association of Directors of Medical Student Education in Psychiatry. At least some of the concern about psychiatric education comes from studies showing that medical students and practicing physicians tend to rate their training in psychiatry as mediocre to poor (1–4). The tendency for medical students to be quite outspoken in their criticism of poor teaching has also precipitated reexamination of many educational programs (5). Other factors contributing to the rising interest in teaching are the need to attract more medical students into psychiatry residency programs, the appointment of many full-time directors of medical student education, and the popularity of liaison psychiatry, with its associated teaching commitment.

This new wave of interest in educational issues has generated a large number of papers dealing with curriculum organization and design as well as content (6–9). However, very little has been written about the most important part of any program, the teacher. The house officer, as noted by Kaufman (5), serves as the main teacher and the student's closest role model during the clinical clerkship. This important role was recognized in 1978, when APA's Office of Education sponsored a combined meeting of the Association for Academic Psychiatry, the American Association of Directors of Psychiatry Residency Training, and the Association of Directors of Medical Student Education in Psychiatry. The meeting was titled "Teaching the Resident How to Teach." Although this meeting was very useful, it was apparent that little was known of the role of residents as teachers.

This survey was designed to gather information about the teaching activities of residents in psychiatry with specific emphasis on the time involved, their attitudes toward teaching, and their opinions on a variety of other educational topics.

METHOD

We sent questionnaires that we designed to each of the 110 university-based psychiatry programs listed in the 1979 edition of the Association of American Medical Colleges *Directory of American Medical Education*. Each director of residency training was asked to randomly select a first-year resident and a third-year resident to complete and return the questionnaire. The questionnaires were returned anonymously except for inclusion of the first three digits of the zip code, which was done so we could compare the results from different geographical areas.

The questionnaire was designed to elicit information in the following areas: 1) sex, age, year in training, and future career plans of the respondents, 2) attitudes of the residents toward themselves as teachers and toward the role of teaching in a residency program, 3) estimates of the actual amount of time spent teaching and opinions about the "ideal" amount of time one should devote to teaching in a good training program, and 4) ratings of the importance of including certain topics and skills in a program designed to improve the effectiveness of teaching by residents in psychiatry.

TABLE 1
Psychiatry Residents' Responses to Questionnaire Statements About Teaching

Questionnaire Statement	Percent of 136 Responses		
	Agree	Disagree	Not Certain
Training of nonpsychiatric physicians to deal with emotional illness is one of the most urgent needs in medical education	80	7	13
In my role as a resident, I am here to learn psychiatry, not to teach it	6	89	5
First-year residents really don't know enough to teach someone else	13	78	9
The main reason residents are required to teach medical students is to free up time for faculty to do research and other things	6	78	16
Residents should be required to attend courses designed to make them better teachers	32	47	21
Third-year residents don't know enough to teach someone else	0	99	1
Questions pertaining to education should be included in Board examinations	22	48	30

RESULTS

One hundred sixty-four (75%) of the questionnaires were returned. However, 28 of these were discarded because of incompleteness or misinterpretation of instructions, leaving 136 complete questionnaires. The data were divided into the following groups for analysis: total sample, male and female respondents, first-year and third-year respondents, eastern United States (zip code digits 000–299), middle United States (zip code digits 300–799), and western United States (zip code digits 800–999). In general, the responses of each of these groups were quite similar; there were only a few significant differences, which will be discussed below. The mean age of all respondents was 29.40 years; first-year residents averaged 28.13 years of age, and third-year residents averaged 30.27 years of age. There were no significant differences in age between male and female respondents or residents from different parts of the country.

Table 1 shows the agreement and disagreement of the total sample with each of seven statements about attitudes of residents toward teaching. The only significant departure from the overall responses occurred with residents from the western states. Fifty-seven percent disagreed with the statement that first-year residents really do not know enough to teach others, in contrast to the overall 78% who disagreed ($p<.001$, chi-square). Only 14% from the west felt that residents should be required to attend courses designed to make them better teachers, whereas 32% of the total sample agreed with this statement ($p<.01$, chi-square).

TABLE 2
Mean Estimates of Actual and Ideal Teaching Time of 136 Psychiatry Residents

Group Taught	Estimate of Actual Time Spent Teaching per Week (hours)	"Ideal" Amount of Time to Spend Teaching per Week (hours)
Medical students	3.67	4.48
Nurses, occupational therapists, social workers	2.04	2.59
Psychiatry residents	1.45	3.01
Nonpsychiatric physicians	1.61	3.22
Total	8.77[a]	13.30[a]

[a]The difference between the means was significant at the .01 level (chi-square).

Table 2 shows the findings of several items on the questionnaire designed to gain information about how much time the residents spent teaching medical students, nurses, occupational therapists, social workers, psychiatric residents, and nonpsychiatric physicians. They were also asked to indicate what they thought was an ideal amount of time to devote to each of these activities. There was a significant difference in each case: estimates of actual time spent were considerably lower than the residents felt they should ideally spend teaching. Overall, the group estimated that they spent about 9 hours a week in teaching activities and that two-thirds of that time was devoted to medical students, nurses, occupational therapists, and social workers. The smaller amount of time spent teaching nonpsychiatric physicians is surprising in view of the recent emphasis on the educational component of consultation/liaison work. First-year residents are often not involved in consultation and liaison, and one might suspect that their responses may have lowered the overall result. However, comparison of results shows no significant difference between first- and third-year residents.

The residents were also asked to estimate the percent of time in each year of training that they felt should be devoted to teaching. The results show a range of 9% in the first year, 14% in the second year, 21% in the third year, and 28% in the fourth year of training. If one assumes a 60-hour work week, these percents translate into about 5 hours per week in the first year, increasing to 17 hours per week in the fourth year, and an overall average of 10.8 hours per week for all 4 years.

In spite of the rather large amount of time these residents spent in teaching, they were not particularly interested in attending training sessions to make them better teachers. Only 32% felt they should be required to attend courses to make them better teachers, and only 13% indicated they had received any training designed to improve their teaching. Feedback regarding

teaching skills from experienced instructors was apparently uncommon. Two-thirds of the residents indicated that they had received written feedback from students about lecture presentations; however, very few had received any type of criticism or suggestions from their faculty supervisors.

The respondents' opinions about what skills are important in making them better teachers followed the traditional lines of medical education. Interviewing, differential diagnosis, psychopharmacology, and emergency psychiatry received the highest ratings of importance; the residents were less concerned with developing their skills in preparing written materials, self-instructional courses, or the use of videotapes, movies, or other technological aids.

DISCUSSION

These results indicate that most psychiatric residents have a strong commitment to teaching and are willing to devote a considerable amount of time to educational activities. Our respondents spent almost 2 hours per day teaching and felt that this should be increased to more than 3 hours per day, especially in the last year of training. This amount of time would make teaching one of the major components of any residency program; however, it appears that very little if any effort was made to determine if these residents were doing a satisfactory job or to provide training designed to make them better teachers. The reason for this is probably the residents' own lack of motivation in asking for courses to make them better teachers and the likelihood that most faculty prefer to teach clinical subjects. It is unfortunate that many of the residents were not concerned with improving their skills in preparing written materials and using audiovisual aids. Both of these are relatively easy to teach and enhance the learning of some topics difficult to present orally.

Residents from western states seemed to feel less capable of teaching in the first year of training and, paradoxically, were less interested in attending courses designed to make them better teachers. The reason for this difference in attitudes is not clear from the data obtained in this study.

The old adage, "See one, do one, and teach one," although possibly appropriate for some specialties, is simply not adequate for psychiatry, with its abstract concepts, invisible pathology, and need for confidentiality. We must improve the communications skills of residents (and faculty) if we are to alter the frequent complaints of poor teaching in psychiatry.

CLINICAL AND RESEARCH REPORTS

This section contains 1) new research findings, including preliminary data from pilot studies, either clinical or laboratory; 2) worthwhile replication studies; 3) case reports that describe a truly new syndrome or cast new light on established ones; and 4) case reports that indicate a new therapeutic procedure of potential value or call attention to adverse effects of drugs or previously unreported complications of therapeutic interventions. Program descriptions and literature reviews cannot be printed in this section. Criteria for format are listed in "Information for Contributors" in each issue; papers that do not adhere to these criteria will be returned to the author.

Intoxication Associated with Lithium and ECT

BY MICHEL R. MANDEL, M.D., JOSEPH MADSEN, ALEXANDER L. MILLER, M.D., AND ROSS J. BALDESSARINI, M.D.

Administration of lithium carbonate during a course of ECT has recently been associated with the development of delirium in a few cases (1-3). Whether a specific ECT-lithium interaction is responsible for this toxic state is unclear, and a mechanism of action has not been elucidated, although increased entry of Li^+ into the brain after ECT is one possibility. This report describes two additional cases of persistent delirium following concurrent administration of ECT and lithium and our attempts to evaluate the distribution of Li^+ in laboratory rats given lithium and electroconvulsive shock (ECS).

Case Reports

Case 1. Mr. A, a 55-year-old, right-handed engineer with bipolar affective illness, developed agitation, depressed mood, and ruminative thinking. Amitriptyline (250 mg/day), lithium carbonate (300 mg t.i.d.; serum levels of 0.8-1.2 mEq/liter), and their combination had been given without success before Mr. A was hospitalized on a psychiatric unit. Chlorpromazine (50-150 mg/day) reduced his agitation, but led to sedation and anticholinergic effects. In preparation for ECT, all drugs except 300 mg of lithium carbonate t.i.d. were discontinued 48 hours before beginning ECT. Laboratory values, including serum electrolytes and urinalysis, were all within normal limits; serum lithium was 0.98 mEq/liter. Mr. A was eating and drinking adequately and was fully oriented, alert, and able to perform mental calculations correctly. Right unilateral ECT (175 volts, sinusoidal, 500 milliamperes for 1 second) was given on alternate days and produced seizures lasting 50-60 seconds. Immediately after the third ECT Mr. A demonstrated signs of delirium including confusion, disorientation, and restlessness, but, in contrast to previous treatments, this state failed to clear. The findings from physical and neurological examinations within 24 hours after his third ECT were normal, except for the change in his mental status; serum lithium 3 hours after the third ECT (12 hours following the last dose of lithium) was 0.80 mEq/liter. As this clinical picture persisted, lithium was discontinued; 48 hours later Mr. A was much less confused and somewhat less depressed. ECT was therefore resumed; 4 additional sessions of ECT led to an adequate antidepressant response without further delirium following a usual degree of mild, brief initial postictal confusion. Maintenance lithium was resumed 10 days after completion of the ECT. Two months later Mr. A was well without further cognitive disturbance. He could not recall his early period of hospitalization, but he remembered being discharged from the hospital and had no other evidence of memory impairment.

Case 2. Ms. B, a 67-year-old, right-handed woman with recurrent unipolar major depressive illness that was inadequately responsive to antidepressant drugs, had been successfully maintained for 2 years on lithium carbonate (300 mg t.i.d.; serum levels of 0.6-0.8 mEq/liter). When she became progressively depressed over a 4-week period, she was

admitted for ECT, the most successful treatment for her in the past. The findings from routine physical and neurological examinations and laboratory values, including electrolytes and urinalysis, were normal before ECT. Lithium was continued; following the first right unilateral ECT (200 volts, sinusoidal, 500 milliamperes, 1 second), she developed slurred speech and became disoriented. These dysfunctions improved somewhat over 24 hours after the treatment but worsened after the second ECT 2 days later. Lithium was then discontinued. Serum lithium 24 hours after the second ECT (12 hours after the last dose of lithium) was 0.6 mEq/liter; other electrolyte levels were normal. Within 72 hours she was much less confused. ECT was given four more times without further cognitive disturbance and with good antidepressant effect. Two weeks following the ECT sessions Ms. B resumed a maintenance dose of 300 mg of lithium carbonate t.i.d. without further complications.

Laboratory Studies

Methods. These clinical observations suggested that ECT and lithium might interact to produce delirium, possibly by increased entry of Li^+ into the brain. To test this hypothesis, we conducted two experiments with adult (300–350 g) Sprague-Dawley rats. They were given ECS by ear-clip electrodes after repeated (experiment 1) or single (experiment 2) doses of lithium chloride. Doses of lithium chloride were chosen so that blood concentrations of Li^+ would reach clinically encountered levels (about 1 mEq/liter) 10–12 hours later (4).

In experiment 1 rats were given 4 mEq/kg of lithium chloride in water (intraperitoneally) twice daily for 3 days; a final dose on the morning of day 4 was followed in 30 minutes by a single ECS (5). Controls received only restraint and application of the electrodes, not ECS. All rats were decapitated 60 minutes following the final dose of lithium chloride.

In experiment 2 rats were given 5 mEq/kg of lithium chloride intraperitoneally once only. Controls received no further treatment before decapitation. Those rats receiving ECS (6) 2 hours later were given atropine sulfate (0.2 mg, intramuscularly, 15 minutes before ECS) and succinylcholine chloride (0.2 mg by tail vein). Then an endotracheal tube was inserted into each rat, and it was artificially ventilated during muscular paralysis for 5 minutes before and 10 minutes after ECS. The respirator delivered a 97:3 or 90:10 mixture of O_2:CO_2 at a rate and volume previously found to yield normal arterial pH and pCO_2 with the 3% CO_2 mixture (6). EEG was monitored with bilateral subscalp electrodes and a Grass polygraph. ECS stimuli (150 pulses of 1-millisecond duration at 150 volts over 1 second) were repeated at 10-second intervals. Half of the rats received 3 ECSs, and the others received 10 ECSs in order to evaluate the effects of more intensive stimulation. The paralyzed rats recovered within 10 minutes and were decapitated 30 minutes after ECS (150 minutes after lithium chloride).

Serum was recovered from coagulated blood by centrifugation. Whole brains were removed, cleaned of vessels and blood, homogenized in trichloroacetic acid (10%, weight to volume in experiment 1) or a detergent in water (Acationex, 0.02% by volume in experiment 2) and centrifuged at 60,000×*g* for 20 minutes. The concentration of Li^+ was determined in the resulting supernatants of tissue extract (diluted 12-fold) or in serum (diluted 40-fold with deionized water) by atomic absorption spectrometry (Perkin-Elmer) (4); standards included known amounts of lithium chloride in appropriately diluted serum or tissue extracts from normal rats, and recovery was quantitative.

TABLE 1
Effect of Electroconvulsive Shock (ECS) on Lithium Distribution in the Rat

	Brain Concentration of Li^+ (mEq/kg)		Ratio of Brain to Serum Concentration of Li^+[b]	
Condition[a]	Mean	SE	Mean	SE
Experiment 1[c]				
Control rats	1.92	0.32	0.58	0.08
ECS rats	2.07	0.43	0.61	0.12
Experiment 2[d]				
Control rats	1.36	0.06	0.40	0.02
ECS rats	1.38	0.04	0.45	0.03

[a]There were 8 to 12 rats per group in each experiment.
[b]Ratio of brain to serum concentration of Li^+ was determined for each rat, and means were computed from the logarithm of each ratio; no difference between control and shocked rats was statistically significant by Student's *t* test.
[c]Four days of lithium chloride; unmodified ECS.
[d]Acute lithium chloride; modified ECS.

Results

There were no significant increases in brain concentrations of Li^+ or in the ratio of brain to blood levels after ECS (see table 1). There was also no difference between ECS given 3 times versus 10 times or ventilation with 3% versus 10% CO_2 in experiment 2; thus, these data were pooled. In addition, the use of atropine and succinylcholine, as encountered in clinical ECT, had no effect on the distribution of Li^+ between blood and brain. Ratios in experiment 1 were higher due to the use of a 4-day treatment regimen that leaves some Li^+ in the brain before the final dose of lithium chloride.

Another laboratory reported that the efficiency of extraction of radio-labeled ions by brain, per unit blood flow, was unchanged by ECS but suggested that *total* extraction was increased due to increased blood flow during and closely after ECS (7). Thus, it seemed reasonable to hypothesize that the equilibration of Li^+ between blood and brain might be accelerated by ECS. In order to maximize the chances of observing increased entry of Li^+ into rat brain after ECS; we selected those times after the rats received doses of lithium chloride so that large differences would exist between blood and brain concentrations of Li^+ (4) because later times closer to steady-state conditions would tend to obscure influences of ECS due to accel-

erated blood-brain exchange of Li^+ (7). Moreover, we included conditions of intensive stimulation and the addition of high concentrations of inspired CO_2 in order to maximize the chances of observing changes due to increased cerebral blood flow (7).

Conclusions

Even under rather extreme conditions, no significant increases in the accumulation of Li^+ in the brain or efficiency of its entry from blood to brain could be detected. Thus, our present laboratory models do not support the hypothesis that electrically induced seizures, or their modification by drugs used in clinical ECT, significantly increase the levels or entry of Li^+ in the brain even at times of maximum differences between blood and brain concentrations and during conditions of strong stimulation and large elevations of cerebral blood flow. We suggest, rather, that the occasional development of a persistent but reversible organic mental syndrome during the association of ECT with lithium therapy, as in the case reports described above, is not likely to be a consequence of markedly increased brain levels of Li^+. Other, possibly additive but reversible, toxic effects of the two treatments in susceptible individuals should be considered.

Treatment of the Child Pornography Patient

BY ULRICH C. SCHOETTLE, M.D.

Although there has been a burgeoning interest in child abuse, especially sexual abuse, little has been written on child pornography (1–4). Until recently the literature was devoid of case material about adults and children involved with child pornography either as viewers or as participants (5). In this paper, child pornography refers to any visual reproduction of the sexual abuse of children. With the aim of addressing special treatment issues, I will present a case report of an early pubescent girl involved in a child pornography ring.

Case Report

Kathy, a 12-year-old girl, had casual nonsexual meetings with two pornography ring members for at least 2 years before her first encounter with pornographic pictures at age 8. Subsequently, she, her siblings, and a number of boys and girls engaged in photographed oral, anal, and genital sexual acts with adults and each other during a $3\frac{1}{2}$-year period. After police investigation of the child pornography ring, Kathy and her family were referred to our sex abuse clinic for psychiatric evaluation and weekly therapy.

At the first session Kathy's complaints related to feeling guilty about being accused of involving her younger siblings in the sexual exploration schemes. Kathy said she had threatened to kill herself the day neighborhood children harassed her family after the news media exposed her family's participation in the ring. Initially she denied all pleasurable feelings associated with the sexual interactions, and she said that throughout her participation in the pornography ring she feared recrimination from the perpetrators.

Kathy was a short-statured, verbal, early pubescent girl who wore age-appropriate clothing. Although she was initially anxious and depressed, she subsequently demonstrated an appropriate range of affect. Psychological testing revealed she had a low-average intelligence; her projective testing themes included helplessness, depression, victimization, and a denial of, or pulling away from, sexual concerns. Kathy had no history of psychotherapy, psychosis, drug abuse, or major medical illness. Her developmental milestones were age appropriate, except for the deviant sexual experiences.

The family's history was remarkable in that when Kathy was 2 years old, her alcohol-abusing father allegedly threat-

ened to kill her with a knife during a family argument. No further history of sexual or physical abuse was reported. The mother's second marriage was likewise beset with turmoil but with no demonstrable abuse. Kathy's mother described her own youth as one of being unloved and physically abused; she ran away to marry Kathy's father at age 15. Kathy's mother repeatedly denied all knowledge of her children's involvement in pornography.

Kathy's history and presentation were consistent with a diagnosis of sexual deviation with associated depression. After the initial family evaluation sessions, the sexual abuse clinic staff felt that each family member warranted individual therapists because of unique individual dynamics and significant differences in age. The children were primarily seen in psychoanalytically oriented play therapy. Kathy's mother had supportive psychotherapy with an emphasis on role modeling. Neither the biological father nor the stepfather was available for intervention. Biweekly therapist meetings coordinated treatment strategies and allowed for clarification of interagency communication, especially regarding legal matters.

Discussion

There appear to be three phases in treating children involved in pornography. In the first phase, the sexual "ticket of admission" phase, patients are often asked to give detailed accounts of their sexual encounters to police investigators, the court system, social service agencies, and also the medical/psychiatric community for purposes of initiating treatment as well as prosecuting perpetrators. Concurrent with a flood of emotion (6) and ambivalent relief that the secret is broken (7), guilt feelings begin to emerge (5, 7, 8). Kathy felt guilty for being declared an innocent minor by the juvenile justice system while her adult companions were incarcerated.

In early treatment sessions, the pornography victim relatively freely discusses sexual matters, albeit there are often giggles, smirks, and an avoidance of eye contact. As a transference relationship develops, the patient may deny earlier statements of sexual involvement in hopes of seeking the therapist's positive regard. This is in marked contrast to the more typical early adolescent patient, who is often initially reticent to reveal sexual material but becomes less inhibited as a therapeutic alliance develops.

In the second phase of treatment, the ambivalent phase, the issue of sexual promiscuity assumes less importance. Disturbed early parent-child relationships come to the forefront. For instance, Kathy repeatedly spoke and dreamt of her ambivalent feelings toward one of the ring members whom she regarded as "warm, giving, and father-like," yet he allegedly exploited the children sexually. Paradoxically, the child's anger over repeated sexual assaults is not necessarily directed at the offenders but rather at the failure of the mother and the absent father to protect the victim from adult transgressions (7). In addition, there is an active attempt by the child to split off the good and bad parts of herself and of significant adults.

In the third phase of treatment, the integration phase, there is a gradual resumption of the normal developmental process. Sexuality becomes integrated into the child's whole personality (5). The patient has developed additional nonsexual ways of communicating with peers and adults. Now, the child is able to appreciate good and bad qualities in herself or himself and others.

Throughout treatment, countertransference issues can hamper effective intervention (9). Rescue fantasies, punitive urges, curiosity, and fears of over- or undersexualizing the therapeutic transference relationship are recurrent countertransference themes. The child's cathartic description of the sexual transgressions can be stimulating, enticing, and also threatening to the therapist, who attempts to be objective and empathetic while listening to a barrage of sexually laden transference material.

Although there are unique issues in the treatment of pornography ring victims, in this case standard methods of psychoanalytically oriented psychotherapy proved useful in eliciting dynamics and intrapsychic conflicts and in working through issues of resistance and transference. The child pornography victim, although emotionally and physically traumatized, appears to be able to reintegrate herself or himself into an age-appropriate lifestyle.

ECT and Cardiac Patients with Pacemakers

BY GEORGE S. ALEXOPOULOS, M.D., AND RICHARD J. FRANCES, M.D.

ECT is likely to be indicated in cardiac patients with pacemakers because heart disorders occur most frequently in middle or advanced age, a period of high incidence of depression (1). We discuss below various considerations involved in using ECT on patients with pacemakers and describe a successfully treated cardiac patient with a pacemaker.

Case Report

Mr. A, a 78-year-old man with a history of bipolar affective disorder, was admitted to the hospital during an episode of severe depression with endogenous features. For 1 month his symptoms failed to respond to 250 mg/day of imipramine. Mr. A's tricyclic blood level of 74 ng/ml was not in the range (>180 ng/ml) associated with frequent antidepressant response. He also had at least 1 year's history of chronic slow atrial fibrillation probably due to arteriosclerotic heart disease. One year before this admission he had a transvenous permanent unipolar demand pacemaker (CPI 0505) implanted following two instances of syncope; during each syncope Mr. A's ventricular rate was 45 beats per minute.

Because of the severity of Mr. A's depressive symptoms and his poor response to tricyclics, he was treated with five bilateral ECTs (140 volts for 1 second), and he had an excellent antidepressant response. Before ECT was applied appropriate X rays and ECGs were taken of Mr. A under different body positions to establish that the pacemaker's electrode was in place and operating properly. He was medicated before each treatment with 300 mg of pentobarbital i.v. and 60 mg of succinylcholine i.v., and his heart was monitored by a regular ECG machine that was plugged in immediately after ECT was delivered. Precautions were taken to keep Mr. A from coming into contact with a low resistance electrical pathway. The ECT room had an insulated floor. As a precaution in case Mr. A developed a prolonged low pulse rate a magnet was available; it could be placed on the pulse generator to convert the demand pacemaker to a fixed rate if necessary. The only complication we observed was the development of infrequent premature ventricular contractions that lasted for a period of 3–6 minutes following each ECT. Although premature ventricular contractions inhibited the pacemaker, Mr. A's pulse rate was never reduced for any significant period, and thus no intervention was required.

Discussion

Implanted cardiac pacemakers are used for a variety of heart diseases in patients who have impaired electrical conduction resulting in dangerously decreased cardiac output (1). Three main types of pacemakers are used—fixed-rate pacemakers, synchronous pacemakers that are triggered by R or P waves, and demand pacemakers that are inhibited by R or P waves (1). Use of ECT on patients with pacemakers requires certain considerations.

A high percentage of ECT-induced arrhythmias result from vagal discharge. Premedication with atropine is unnecessary because the pacemaker protects the patient from vagotonic arrhythmias (2–5). Atropine is relatively contraindicated in patients with fixed-rate pacemakers. The atropine-induced tachycardia increases the chance of competition of heart beats with pacemaker beats and thus may lead to dangerous arrhythmias (4, 5).

During ECT only a minimum amount of electricity reaches the heart because the body tissues have high resistance. However, if the insulation of an electrode of the pacemaker is broken or if the patient is in contact with a low resistance pathway, e.g., an improperly grounded monitor or an assistant in contact with the patient and a noninsulated floor, a large current will pass through the heart and may result in ventricular fibrillation and sudden death (4, 6). Therefore, patients should be examined for intermittent pacing related to body posture, and appropriate chest X ray films should be taken to insure that the electrode's insulation is intact. Heart monitoring may be done safely by telemetry, by a battery-operated ECG machine, or by a regular ECG machine that can be plugged in immediately after ECT is delivered.

The pacemaker is not affected by ECT discharge because it has a built-in protection for large electrical potentials (4). However, skeletal muscle potentials that occur during ECT may fall within the range of the pacemaker's sensing circuit and inhibit the demand pacemakers (7). For this reason it is necessary sometimes to convert the demand pacemaker to a fixed-mode pacemaker if severe bradycardia occurs. The majority of pacemakers have a magnet-activated switch that allows this conversion to be made by placing a magnet over the pulse generator. The pacemaker returns to a demand mode when the magnet is removed. The magnet-activated switch can also be helpful in evaluating whether the pacemaker is capable of providing the programmed rate (8). The magnet may be used prophylactically on patients who have manifested pacemaker inhibition during previous ECTs.

Approximately 78% of patients with heart disease develop premature ventricular contractions during ECT (2, 3). These contractions may compete with fixed-rate and synchronous pacemakers, and thus they increase the chance of the patient's developing dangerous arrhythmias. If premature ventricular contractions lead to ineffective heart contractions, as occurred with Mr. A, the contractions may inhibit the function of the demand pacemaker and result in prolonged pulse pauses. This complication is relatively benign and can be effectively treated by converting the demand pacemaker to fixed mode if severe bradycardia occurs. Antiarrhythmic drugs like procainamide, quinidine, and propranolol have been used prophylactically in order to avoid arrhythmias following ECT (9, 10); these drugs may be used prophylactically in patients who developed dangerous arrhythmias during previous ECTs.

Tricyclic antidepressants may also be used safely in cardiac pacemaker patients because the pacemaker protects against bradyarrhythmias due to conduction defect. The sinus tachycardia due to tricyclics' anticholinergic properties is not a problem for those patients with A-V block, a group that constitutes the majority of patients with pacemakers. Certainly these patients are at risk for ventricular tachycardias, but it is questionable whether this risk is higher than for patients without a pacemaker. The decision to use tricyclics or ECT depends on a clinical judgment that takes into consideration the patient's psychiatric indication and the patient's heart condition.

ECT is a reasonably safe procedure in patients with pacemakers if the following precautions are taken before treatment begins: 1) the clinician is aware of the nature of the patient's heart disease and the type and properties of the pacemaker used, 2) appropriate X rays and ECGs are taken of the patient to establish that insulation of the electrodes is intact, and that placement of the electrodes is proper, 3) a magnet is available to convert demand pacemakers to fixed mode if necessary, 4) premedication of the patient with atropine is avoided whenever possible, 5) every precaution is taken to keep the patient from coming into contact with a low resistance pathway, and 6) the patient's heart is monitored.

Cimetidine Toxicity Manifested as Paranoia and Hallucinations

BY LAWRENCE E. ADLER, M.D., LEE SADJA, M.D., AND GREGORY WILETS, M.D.

When cimetidine, an H_2-receptor antagonist, was first released as treatment for peptic ulcer disease, no significant CNS side effects were noted (1). Investigators considered its major action to be a competitive inhibition of histamine type-2 receptors in the gastrointestinal tract that reduced acidity levels by interfering with the action of histamine. During the past few years there has been an increasing number of reports in the English and American literature of acute confusional psychoses associated with cimetidine toxicity. This literature was reviewed by Barnhart and Bowden (2). Predisposing factors include high-dose medication, older age, preexisting psychiatric illness, poor renal function, cerebral impairment, and simultaneous treatment with psychotropic medications. Recently we observed a somewhat different presentation of CNS cimetidine toxicity occurring in a paranoid patient who experienced vivid hallucinations.

Case Report

Mr. A, a 51-year-old man, underwent an aortofemoral bypass operation for claudication. He had no other medical problems, history of drug or alcohol abuse, or previous psychiatric treatment. Mr. A had an uncomplicated postoperative course except for minor GI bleeding. Routine postoperative medications included suppositories, cephalothin sodium, meperidine hydrochloride, 100 mg i.m. every 3–4 hours, and hydroxyzine pamoate, 25 mg i.m. every 3–4 hours. Thirty-six hours after the operation, Mr. A received a single 300 mg-dose of cimetidine intravenously for minor GI bleeding. Over the next 72 hours, Mr. A received 9 doses of cimetidine, 300 mg p.o.

Twenty-four hours after cimetidine therapy was begun, Mr. A became belligerent but responded to reassurance. His physician discontinued meperidine hydrochloride and hydroxyzine pamoate. Forty-eight hours after the initiation of cimetidine therapy, Mr. A became extremely agitated, with visual and auditory hallucinations that he said were "like pornographic movies." He also had difficulty finding his room. Sixty hours after the initiation of cimetidine therapy, Mr. A's visual hallucinations subsided. His physician then requested a psychiatric consultation.

Mr. A was extremely paranoid but revealed no major abnormalities on formal mental status examination. He was oriented to time, person, and day of the week, but missed the date by 2 days. He could recall 3 objects after a 5-minute time lapse. His digit span was 7 forward and 3 backward; he was later able to recall 5 backward. He performed serial sevens correctly but had some difficulty concentrating. Mr. A had a normal speech pattern, his judgment was intact, and he could abstract proverbs well.

We discontinued cimetidine, gave Mr. A 1 mg of haloperidol p.o., and transferred him to the psychiatric service. His psychosis resolved within 36 hours of discontinuation of cimetidine; Mr. A received no further psychotropic medication.

Discussion

Previous reports of cimetidine toxicity have emphasized the patients' confusional state, bizarre speech, and amnesia for the episode. In contrast, Mr. A demonstrated a relative lack of confusion behaviorally and on formal mental status examination. His speech was normal and he had no amnesia. The most striking features of Mr. A's cimetidine toxicity were paranoid delusions, with visual and auditory hallucinations that persisted after the resolution of his initial confusional state. Mr. A did not exhibit any of the predisposing factors to toxicity, although one might speculate that given the severity of the atherosclerotic process in his femoral arteries, there might be subclinical cerebral artery disease.

From this case report it becomes apparent that cimetidine toxicity can trigger a predominantly paranoid psychosis that must be differentiated from other functional or organic paranoid psychoses. Physicians treating patients with cimetidine should be alert to prodromal personality changes, like Mr. A's sudden belligerence, as possible indications of impending psychosis.

A Case Report of Lorazepam Withdrawal

BY RONALD B. STEWART, M.S., RONALD B. SALEM, AND PHILIP K. SPRINGER, M.D.

Reliable reports of true addiction to benzodiazepines have existed in the medical literature since 1961. Hollister and associates (1), in the first published report on the topic, produced signs of withdrawal in 10 of 11 subjects who had been given high doses of chlordiazepoxide. These symptoms did not appear until the third or fourth day following discontinuation of the drug and peaked on the fifth day. Most published reports of benzodiazepine withdrawal in this country have involved long-acting agents such as diazepam and chlordiazepoxide; however, there are a few reports (2, 3) involving oxazepam, a short-acting agent and more recently one report involving lorazepam. Benzodiazepines have a shorter half-life, and theoretically they should produce a more abrupt onset of withdrawal because discontinuation should result in a rapid fall of plasma levels.

Received April 18, 1980; accepted May 29, 1980.

We will describe a patient who experienced an apparent withdrawal reaction after ingesting large doses of lorazepam.

Case Report

Ms. A, a 51-year-old woman, was admitted to the inpatient psychiatry facility of the Shands Teaching Hospital with a referring diagnosis of involutional depression. She complained of insomnia, fatigue, and nervousness, and stated she no longer looked forward to things. Ms. A had noticed these symptoms 3–4 years earlier; they were mild initially but gradually worsened.

Ms. A's medications at the time of admission, according to her recount, included 75 mg of imipramine h.s., 1 mg of lorazepam t.i.d., and 1.25 mg/day of conjugated estrogens. For 4 years she had used increasing doses of diazepam, but when she developed a problem of habituation, her prescription was changed (4 months before her admission) to lorazepam.

Ms. A's initial physical examination was within normal limits. Her mental status examination on admission showed a normal thought process, and she was alert and oriented; however, her affect was flat. Ms. A's laboratory studies were within normal limits except for a mildly elevated lactate dehydrogenase.

On the evening of her admission Ms. A began to complain of progressively worsening nausea, which did not respond to repeated doses of prochlorperazine i.m. The nausea persisted for about 36 hours. Approximately 48 hours after admission Ms. A became very disoriented and rigid, with her head tilted back; she maintained catatonic stances and would not respond to verbal commands. She also displayed a staggering, stumbling gait disturbance and clutched at air, walls, and other objects for support. By the fourth hospital day these symptoms disappeared and Ms. A stated that during the last 2 days her body "refused to do what my mind asked it to do."

On the fourth day of Ms. A's hospitalization her mental status cleared, and a drug history obtained from her revealed that she may have been abusing lorazepam. A phone call to her local pharmacy revealed that Ms. A had received a prescription two months earlier for 100 2-mg lorazepam tablets with directions to take 2 mg of the drug q.i.d. That same afternoon she returned to the pharmacy for a refill, stating she had misplaced the first vial of medication. She returned to the pharmacy approximately every 10 days for a refill of 100 tablets until she was admitted to our unit. A blood sample obtained the morning following admission (18 hours after admission) was sent for analysis and showed a lorazepam level of 31 ng/ml. Because the blood sample was sent to an out-of-state laboratory, results of this analysis were not made available to the staff until after Ms. A had been discharged.

Ms. A remained in the psychiatric unit for 2 weeks and was treated with imipramine. No further episodes of bizarre behavior were noted, and she was discharged and seen thereafter by a local psychiatrist.

Discussion

Withdrawal symptoms after discontinuation of benzodiazepines have been noted in the medical literature for nearly 20 years. Diazepam and chlordiazepoxide have been noted to induce withdrawal symptoms 3–4 days following discontinuation of medication. Although little information exists concerning withdrawal from short-acting benzodiazepines, the pharmacokinetic properties of lorazepam suggest that signs and symptoms would occur sooner after discontinuing use of this drug than with longer-acting agents. Most benzodiazepines have long half-lives and active metabolites that allow for a gradual reduction of blood levels. The half-life for lorazepam is approximately 12 hours, and no metabolites of major importance other than lorazepam glucuronide have been found with this drug (4, 5).

The rapid appearance of gastrointestinal symptoms observed in Ms. A would be expected after discontinuation of lorazepam. It was not clear when she took the last dose of lorazepam; however, 18 hours after admission her drug level was 31 ng/ml. Based on this drug's half-life, her lorazepam level at the time of admission could have been more than 100 ng/ml. Although Ms. A's mental status changes and physical condition could have resulted from a hysteric reaction, the history and blood level data make drug withdrawal a more likely etiology.

This case report should serve to alert physicians to the importance of obtaining an accurate medication history of patients who have a potential for excessive or long-term use of benzodiazepines. It should also be apparent that the newer, short-acting benzodiazepines also have dependence and withdrawal potential.

Changing Perceptions of the Mental Health Needs of Inmates in Local Jails

BY HENRY J. STEADMAN, PH.D., AND STEPHEN A. RIBNER

The complex relationship between mental illness and crime, which has vexed researchers and policy makers for centuries, has taken on renewed importance during the current controversies over changing mental health statutes and their impact on the criminal justice system. Correctional administrators, especially those at local jails, strongly contend that their facilities have become depositories of persons who should be, and formerly would have been, in mental hospitals. Several clinicians support these observations (1-3). Furthermore, the mental health services in criminal justice settings, especially in local jails, are receiving new attention from the American Medical Association Standards for Psychiatric Services in Jails and Prisons and in various journal articles (4).

At the same time these mental health problems are being discussed in a criminal justice context, the staffs at state mental hospitals are concerned because recently admitted patients are now more agitated, hostile, and assaultive (5). In at least one state's mental hospitals the proportion of men with previous arrest records has dramatically increased over the past 30 years (6). Thus, while correctional administrators see themselves as inundated with mentally ill offenders, state mental hospital staffs perceive a significant increase in newly admitted patients who have problems associated with violence—problems that could or should have been handled by the police. Because these views have been expressed frequently by many highly respected professionals in the correctional field they must be considered seriously. In the data reported here we attempt to clarify the accuracy of the correctional staffs' perceptions that the mental health needs of their inmates are changing.

Method

The data reported here were drawn from a larger study (7) of all persons released to Albany County from New York state prisons and the local Albany County Jail in 1968 and 1975. We obtained each offender's mental hospital history from state mental hospitals as well as "rap sheets," which included a complete criminal history as well as data on the offender's subsequent criminal behavior for the first 18 months after his or her release. The previous mental hospitalizations of these offenders may be underestimated because only state mental hospitalization data were available; however, this will not distort any differences across our study groups or time periods.

Results

In 1968, 167 offenders were released from correctional institutions to Albany County—91 inmates from state prisons and 76 inmates from the local jail. In 1975, 252 offenders were released—76 inmates from the state prison and 176 inmates from the local jail. We found that 93% of all offenders in 1968 and 90% in 1975 were men; they had a mean age of 32 years and 28 years, respectively; and in 1968 and 1975 the percentage of black inmates was 42% and 49%, respectively.

We examined first whether the proportion of inmates with previous mental hospitalizations released from state and local correctional facilities had increased from 1968 to 1975. We found no consistent or statistically significant trends. In 1968, 19% (N=17) of the offenders from state prisons had previous mental hospitalizations and in 1975 only 13% (N=10) had a previous mental hospital record. Of the 76 offenders released in 1968 from the county jail, 9% (N=7) had prior mental hospitalizations and 12% (N=21) had such histories in 1975.

Even though there was a rise of 3% in the number of inmates with prior mental hospitalizations released from the local jail, this rise would not explain the dramatic rise in the perceptions of the jail staff that they were seeing more mentally ill inmates. Similar data also have been reported for Colorado; 14% of the inmates admitted to the Denver County Jail in 1974 had had prior inpatient hospitalizations (8). In addition, we found that for those inmates with mental hospitalization histories released from the county jail, the average number of previous admissions to a mental hospital increased from 1.9 admissions in 1968 to 4.1 admissions in 1975. For the state prisoners the admissions rose from 1.5 admissions in 1968 to 2.9 admissions in 1975. Thus, at the local county jail level there is modest empirical support for the altered perceptions of the correctional staff, but the empirical data do not support the vast increase in the perception of the problem. It may be that the same offenders are coming through both systems more often.

Presented at the 133rd annual meeting of the American Psychiatric Association, San Francisco, Calif., May 3-9, 1980. Received Jan. 7, 1980; revised May 5, 1980; accepted June 12, 1980.

This research was funded in part by grant MH-17431 from the National Institute of Mental Health's Center for Studies of Crime and Delinquency.

Copyright © 1980 American Psychiatric Association 0002-953X/80/09/1115/02/$00.50.

We analyzed next the relationship between the mental hospitalization records of the offenders and subsequent crimes committed by them. We could find no relationship. In 1968 3.5% of the state and local offenders without prior mental hospitalization were arrested for violent crimes and 4.2% of those with previous mental hospitalizations were arrested for violent crimes. The proportion of offenders arrested for violent crimes and released in 1975 increased to 16.1% of the offenders with prior mental hospitalizations and 12.7% of the offenders without prior mental hospitalizations. Clearly, however, neither of these differences is of any consequence. There were no substantial differences among the offenders rearrested for violent crimes based on their previous mental hospitalizations. There was also no relationship between a history of state mental hospitalizations and subsequent arrests made within 18 months after the offenders were released.

It is difficult to determine whether the psychopathology of inmates is increasing as a result of more restrictive civil commitment statutes or if correctional administrators have a new set of expectations about psychiatric contributions to correctional institutions. There is little empirical evidence to show that the mental health problems of inmate populations at local or state correctional institutions have changed, and in a very limited way the data presented here suggest that the changes may have occurred in the perceptions and expectations of the correctional staffs rather than in the characteristics of the inmates. More empirical evidence is required before one can accept at face value the claims of correctional administrators and some clinicians about the radical changes in the mental health needs of U.S. jail inmates.

It is unfortunate that often the introduction of a psychiatrist into the jail is seen by the correctional staff as the sole solution to a wide variety of social and community problems. The limits of direct psychiatric intervention for disturbed inmates must be communicated to the correctional staff so that inappropriate expectations by the correctional staff will not doom the psychiatric services to failure in their eyes and contribute to the truncated development of the full range of social support services that are needed. As stated by Nielsen (4), it is important to articulate how the psychiatric services are related to other community mental health services. Contrary to the expectations of the public and often correctional staffs, psychiatric treatment goals do not generally include lowering the recidivism rate. Nevertheless, if a former inmate is rearrested, the failure is often attributed to the mental health treatment, which is usually incidental to the crisis intervention services that characterize the jail or prison treatment.

Thus, it is important that the goals and promises for mental health programs in jails and prisons be made very explicit. The character of the inmates' needs may not have changed to the extent that they have been perceived to have changed, but this fact does not diminish the current mental health needs of inmates. It simply means that the mental health problems that were found in prisons previously still remain.

Prolactin Changes in Major Depressive Disorders

BY GREGORY M. ASNIS, M.D., R. SWAMI NATHAN, M.D., URIEL HALBREICH, M.D., FREIDA S. HALPERN, M.A., AND EDWARD J. SACHAR, M.D.

According to current knowledge, prolactin secretion is controlled by the inhibitory effect of dopamine and the stimulatory effect of serotonin (1). Alterations in basal prolactin secretion may therefore indicate central neurotransmitter changes. There have been inconsistent reports about basal prolactin levels in depression (during which hypothesized neurotransmitter deficits occur). Some researchers have reported no change in prolactin levels, while others have reported a small increase compared with levels in either normal subjects or in the same patients after recovery (2). We assessed basal prolactin levels in a group of depressed patients during illness and after recovery and found a small but significant increase in basal prolactin after recovery.

Method

We evaluated 19 medically healthy, depressed inpatients (15 women, 4 men), who gave informed consent to the research. Their mean age was 48.4 years±11.4 years. All of our patients met Research Diagnostic Criteria for major depressive disorder, endogenous subtype (3) and had Hamilton Depression scores (4) of greater than or equal to 18 (mean Hamilton score was 28.3±6.5). We determined the patients' basal morning plasma prolactin levels after at least 10 days of drug-free hospitalization and again approximately 6 weeks later after full clinical recovery (Hamilton score of less than or equal to 8). All but 3 patients were receiving antidepressant medication at the time of their clinical recovery. Seven patients received desipramine, 175–400 mg/day; 5 patients received imipramine, 100–375 mg/day; 1 patient received doxepin 150 mg/day; and 3 patients received Mianserin (a tetracyclic), 120 mg/day.

TABLE 1
Comparison of Basal Prolactin Levels in 19 Patients During Depression and After Recovery

Time of Blood Samples	Basal Prolactin Levels (ng/ml)			
	During Major Depressive Disorder		After Recovery	
	Mean	SD	Mean	SD
9:00 a.m.	8.7	3.2	12.5[a]	7.2
9:15 a.m.	7.5	3.4	11.3[b]	4.5
9:30 a.m.	7.0	3.2	10.7[b]	4.5

[a] $p<.02$, two-tailed t test.
[b] $p<.001$, two-tailed t test.

Our patients were awakened at 7:00 a.m. but continued to fast from the previous night. At 9:00 a.m. we inserted a cannula with a heparin lock into an antecubital vein and drew 3 blood samples at 15-minute intervals. We immediately centrifuged the samples at 4° C and stored the plasma at −20° C until it was assayed. We analyzed prolactin by homologous double antibody radioimmunoassay (5). We analyzed all samples in duplicate and in one assay. The intra-assay and inter-assay variations were 4.9% and 9.6%, respectively.

Results

Prolactin levels were significantly greater at each baseline point after patients had recovered than during their illnesses (see table 1). After we log transformed the data to equalize the variances, the Student's t test remained highly significant each time. However, even though there was a significant difference in prolactin levels during illness and after recovery, at both of these times prolactin levels remained within normal range. In the male patients prolactin levels ranged from 3.3 ng/ml to 11.2 ng/ml; in the female patients prolactin levels ranged from 4.6 ng/ml to 20.0 ng/ml (except for 1 female patient who had a prolactin value of 36.2 ng/ml during illness after the initial insertion of the cannula, which was most likely a transient stress response).

Discussion

Since all prolactin values, before and after recovery, were in the normal range, and since all but 3 patients were receiving antidepressants at the time of recovery, we could interpret our results in two ways: 1) as a modest but significant reduction in prolactin secretion, associated with depressive illness or 2) as a modest but significant increase in prolactin secretion associated with antidepressant therapy. We are now conducting

further studies of recovered patients after antidepressant withdrawal or of patients before and after ECT-induced remission to clarify this issue.

If we find that relative reduction in prolactin secretion is associated with depressive illness, current controversial knowledge of neurotransmitter regulation of basal prolactin levels would implicate increased dopaminergic tone or possibly decreased serotonergic tone.

If we find that chronic antidepressant therapy modestly elevates prolactin secretion, we could attribute this to increased serotonergic tone or decreased dopaminergic tone. However, there is considerable controversy in the literature about the effect of chronic antidepressant therapy on prolactin secretion (2). Researchers who have assessed prolactin levels before and after chronic administration of tricyclic antidepressants in the same patients noted that amitriptyline and imipramine had no effect on prolactin levels but that clomipramine, a highly serotonergic drug, increased prolactin levels (6, 7). We treated our patients with various agents that had widely different potencies on neuronal serotonin reuptake blockade and little known antagonistic effect on dopamine transmission. All 3 patients who were tested unmedicated after clinical recovery also had increased prolactin levels. The universality of the relative increase we noted in 17 of 19 patients who received different forms of therapy might suggest a relative reduction in prolactin secretion during depressive illness as the most likely interpretation. An underlying mechanism of reduced serotonergic tone during depression would then seem to be the explanation most consonant with current biological concepts of depressive illness and with our incomplete knowledge of neurotransmitter regulation of basal prolactin secretion.

Acetylcholinesterase and Pseudocholinesterase Activities in Anxiety

BY ROY J. MATHEW, M.D., LOUISE L. HSU, PH.D., KAREN M. SEMCHUK, B.S.N., AND JAMES L. CLAGHORN, M.D.

Cholinesterase, the enzyme responsible for metabolic degradation of acetylcholine, is presumed to exist in at least two forms: acetylcholinesterase (true or specific cholinesterase) and propiono cholinesterase (pseudo or nonspecific cholinesterase). Acetylcholinesterase hydrolyzes acetylcholine faster than pseudocholinesterase. Although the function of acetylcholinesterase is thought to be the hydrolysis of acetylcholine, no function has been ascribed to pseudocholinesterase (1).

Anxiety is associated with autonomic imbalance involving both adrenergic and cholinergic systems. Acetylcholine serves as the neurotransmitter at the ganglionic level for sympathetic and parasympathetic systems, motor nerve endings, parasympathetic postganglionic terminals, and sympathetic postganglionic terminals to sweat glands and adrenal medulla; all of these are involved in autonomic arousal. Seemingly, then, imbalances in the cholinergic system should occur in anxiety (2). However, only a few studies have been conducted in this area whereby investigators reported an increase in pseudocholinesterase activity in anxiety (3–5). In this study we examined the levels of true cholinesterase and pseudocholinesterase and compared the levels of anxiety in anxious patients and

[c]Expressed as micromoles per milliliter of plasma per minute.

control volunteers before and after relaxation training sessions.

Method

A total of 15 outpatients, 6 men and 9 women (mean age±SD=38.26±12.03 years) with a diagnosis of generalized anxiety disorder (6), took part in our project. Most of the patients were not receiving any medication when they first contacted our unit; 3 were taking benzodiazepines and none were receiving monoamine oxidase inhibitors. All of the patients underwent a 2-week washout period before their participation in the study. Control subjects, 7 men and 8 women (mean age=32.80±7.92 years) were healthy, drug-free volunteers.

The procedures were fully explained to all potential subjects in lay terms, and we obtained written consent from each of them. At the initial visit physical examinations and routine laboratory tests were performed. The participants were instructed to avoid all forms of medication throughout the study.

Before the relaxation training began, cholinesterase levels and psychological measures were determined at the second visit. During this visit the participants were asked to relax on a couch in a supine position for 35 minutes in a semidark and quiet room. Then enzyme assay blood samples were drawn. At this time the participants also completed the State-Trait Anxiety Inventory (7), which is composed of separate self-report scales for measurement of two distinct anxiety concepts—state anxiety and trait anxiety. State anxiety is conceptualized as a transitory human emotional state or condition that is characterized by heightened autonomic nervous system activity and subjective, consciously perceived feelings of tension and apprehension. Trait anxiety refers to individual differences in anxiety proneness, that is, differences that exist among individuals in their tendency to respond to situations perceived as threatening with elevations in state anxiety intensity.

For the next 4 weeks the participants received 10 to 12 biofeedback-assisted relaxation training sessions lasting 35 minutes each; they were instructed to practice the exercises at home for 20 minutes per day. When the relaxation training was completed, the subjects returned to the laboratory for a posttraining evaluation, which was conducted according to the procedures used during the second visit.

We collected 5–7 ml of whole blood from each subject in a vacutainer containing EDTA; these samples were kept in crushed ice at 4° C for 1–2 hours. Then the sample tubes were centrifuged at 1,700 rpm for 5 minutes at 40° C to separate plasma and red blood cells. Plasma layers were transferred to plastic tubes for assay of pseudocholinesterase. After the platelets were removed from the interface, the red blood cell fractions were washed twice with 4 volumes of normal saline by gentle inversion and centrifugation at 2,000 rpm at 4° C for 5 minutes. The upper saline layers were discarded by aspiration and aliquots of red blood cell fraction were used for acetylcholine assay. All samples were drawn at the same time of day.

Enzyme activity of acetylcholinesterase in red blood cells and pseudocholinesterase in plasma was determined, with only slight modifications, according to the method of Garry and Routh (8). The procedure is based on the liberation of thiocholine from the substrate acetylthiocholine by action of acetylcholinesterase in red blood cell or from the substrate propionylthiocholine by action of pseudocholinesterase in plasma. The thiocholine then reacts with 5, 5′-dithiobis-(2-nitrobenzoic acid) to form the yellow anion of 5-thio-2-nitrobenzoic acid, which is measured at 410 mμ in a Beckman DB-G spectrophotometer.

Results

The patient and control groups were compared by levels of anxiety and enzyme activity using values taken before and after the relaxation training sessions, as shown in table 1. The posttraining session values for anxiety levels were compared with the pretraining ses-

sion values, and significant reductions were found after the training sessions for the index group only ($t=6.75$ and $t=5.89$, $p<.001$, for state anxiety and trait anxiety, respectively). There were no significant differences between groups before and after the relaxation training sessions in acetylcholinesterase and pseudocholinesterase activities. No meaningful correlations emerged when levels of enzyme activities were correlated against state anxiety and trait anxiety scores for the patient and control groups using pretraining and posttraining data.

Discussion

These findings of increased plasma pseudocholinesterase activity and unaltered true cholinesterase activity in anxious subjects substantiate the findings of previous investigators (3–5). The failure of the enzyme levels to decrease with anxiety relief is in keeping with the report by Richter and Lee (5), who found no significant alteration in the enzyme levels following administration of barbiturates. It must be noted that other conditions characterized by autonomic arousal (thyrotoxicosis and insulin shock) have been associated with increased pseudocholinesterase activity (9, 10). Because no physiological function has been ascribed to the pseudo form of the enzyme, the pathological significance of our finding of increased activity in chronically anxious patients is unclear.

These findings seem to suggest that increased plasma pseudocholinesterase activity may be indicative of a constitutional predisposition to anxiety. This possibility is weakened by the absence of significant correlations between trait anxiety scores and pseudocholinesterase activity. However, it must be noted that our finding of decreased trait anxiety scores following relaxation training raises a question about the validity of the trait anxiety score, which is considered a stable characteristic of the Inventory, as an index of constitutional predisposition. No firm conclusions can be drawn about constitutional predisposition to anxiety and plasma pseudocholinesterase based on the findings reported here.

Clonidine for Opiate Detoxification: Outpatient Clinical Trials

BY ARNOLD M. WASHTON, PH.D., AND RICHARD B. RESNICK, M.D.

Recent studies (1, 2) have shown that a single dose of clonidine hydrochloride relieves signs and symptoms of opiate withdrawal and that addicts can be successfully detoxified with clonidine under the close supervision of an inpatient setting. The rationale for testing clonidine's efficacy in opiate withdrawal was based on animal studies showing that increased brain noradrenergic activity associated with opiate withdrawal was markedly reduced by clonidine (1).

The limited efficacy of standard detoxification methods, such as gradual methadone dose reductions, and the fact that clonidine is the only nonopiate drug shown to have specific antiwithdrawal effects underscores the need for further clinical investigation of clonidine's usefulness in opiate detoxification. If clonidine could be used not only for inpatient detoxification but also on an outpatient basis, it might become more widely available to patients and thus play a more significant role in addiction treatment. The inpatient clonidine dose regiment of 17 μg/kg used by earlier researchers (2) generated profound sedation and hypotension in patients, which necessitated keeping them supine at bed rest; therefore, determination of a safe and effective dose regimen for nonhospitalized ambulatory patients must precede any further evaluation of clonidine's suitability for outpatient use.

We have now administered clonidine to 70 outpatients addicted to heroin or methadone. We have found that clonidine is a safe and effective treatment for outpatient opiate detoxification when the dose regimen is individualized and titrated according to each patient's clinical course.

Method

Our subjects were 70 opiate-dependent outpatients who requested detoxification, had been addicted to opiates for at least 2 years, showed no evidence of serious medical or psychiatric illness, and gave informed consent to participate in the study after receiving a full explanation of the experimental procedures. Of the 70 patients, 59 patients were taking clinic methadone doses ranging from 5 mg to 40 mg/day (average dose, 20 mg/day) and 11 patients were using from $10 to $150 worth of heroin a day (average, $45/day). Twenty of the methadone-dependent patients received clonidine in conjunction with gradual methadone dose reductions, and the remaining 50 patients received clonidine after abrupt termination of methadone or heroin.

On day 1 of the study, all patients were instructed to take a 0.1-mg tablet of clonidine every 4–6 hours as needed for withdrawal discomfort. The total daily clonidine dose was then increased on each succeeding day by 0.1 mg or 0.2 mg to a maximum of 1.2 mg according to each patient's blood pressure and symptomatology. This was done to minimize the withdrawal discomfort without generating untoward side effects, such as oversedation and orthostatic hypotension. Clonidine doses were held or decreased in some cases to compensate for sedation or hypotension. Maximum daily clonidine doses averaged 0.8 mg and ranged from 0.3 mg to 1.2 mg. Patients who received clonidine during gradual methadone withdrawal were placed on a methadone dose reduction schedule of 5 mg or 10 mg/week and later switched to placebo methadone upon reaching a zero dose. Patients who switched abruptly to clonidine from heroin or methadone were placed directly on placebo methadone on the first day that clonidine was introduced.

Patients who were able to remain opiate free on clonidine for at least 10 days after their last dose of methadone or heroin, as indicated by opiate-free urines and verbal report, received a naloxone challenge of 2.0 mg i.v. to confirm readiness to begin post-detoxification treatment with the narcotic antagonist naltrexone so that continued abstinence would be fostered (3, 4).

Results

Detoxification success rates, defined by the number of patients who were able to remain opiate free on clonidine for the 10 days necessary to initiate naltrexone treatment, are presented in table 1 for the gradual and abrupt withdrawal procedures. These data show superiority of the abrupt withdrawal procedure as compared with the gradual procedure in helping patients achieve an opiate-free state. The data also indicate that patients who switched abruptly from methadone to clonidine were more successful than those who switched abruptly from heroin to clonidine. In general, patients using large amounts of heroin, i.e.,

TABLE 1
Detoxification Success Rates[a] with Clonidine for 70 Outpatients

Withdrawal Procedure	Patients: Successful N	Successful %	Unsuccessful N	Unsuccessful %	Significance[a]
Gradual, from methadone (N=20)	10	50	10	50	p<.05
Abrupt (N=50)	35	70	15	30	
From methadone (N=39)	31	80	8	20	p<.01
From heroin (N=11)	4	36	7	64	

[a]By chi-square analysis.

$100 worth or more a day, and those taking more than 30 mg/day of methadone, experienced the greatest difficulty in completing detoxification. Clonidine reduced or eliminated most of the commonly reported withdrawal signs and symptoms, such as chills, lacrimation, rhinorrhea, restlessness, muscle pains, and stomach cramps. Lethargy and insomnia were the most frequent and persistent complaints. While taking clonidine most patients reported at least one episode of lightheadedness or dizziness upon standing. Six patients experienced unacceptable dizziness and/or sedation while taking only 0.3 mg/day of clonidine. Because most patients developed a tolerance to clonidine's sedative effect after taking the drug for several days, they required additional nighttime sedation to alleviate persistent insomnia.

Rapid decrements in the daily clonidine dose at the end of the study produced headaches and a reemergence of withdrawal symptoms. These ill effects were avoided by tapering the clonidine dose by 0.1 mg/day or 0.2 mg/day.

Discussion

This clinical study confirms clonidine's antiwithdrawal effects and demonstrates that outpatients can be detoxified with clonidine in a safe, acceptable, and effective manner. Our 80% success rate following abrupt withdrawal of 5–40 mg/day of methadone suggests that clonidine might be superior to the usual methadone dose reduction procedures that have typically shown much lower success rates (5). However, our rather high success rate in this study may have been due in part to nonpharmacologic factors, such as patient selection, daily contact with a supportive staff, and expectations of success with a new treatment. In order to obtain a more definitive assessment of clonidine's efficacy as a detoxification treatment we are now conducting a randomized double-blind outpatient study that compares clonidine and methadone detoxification procedures.

Our clinical experience in this study indicates that clonidine is a highly effective detoxification treatment for outpatients who are taking no more than 30 mg/day of methadone; however, no single clonidine dose regimen is best for all patients. In order to achieve a safe and effective control of withdrawal symptoms with clonidine, the dose regimen must be individualized according to each patient's blood pressure and symptomatology. Some patients are acutely sensitive to clonidine's hypotensive and sedative effects and cannot tolerate dosages large enough to control withdrawal symptoms. In most cases, however, a dose regimen of 0.1 mg or 0.2 mg every 4–6 hours with a larger dose at bedtime provides adequate relief of withdrawal symptoms with little or no untoward side effects.

Our evidence of clonidine's efficacy in opiate detoxification lends clinical support to the hypothesis (1) that noradrenergic hyperactivity is significantly involved in mediating the opiate withdrawal syndrome. This 10-day outpatient clonidine detoxification procedure may be extremely useful in allowing a rapid switch from opiate dependence to drug-free or opiate antagonist treatment without hospitalization.

Differences Between Psychologists and Psychiatrists in the Use of *DSM-III*

BY LESLIE C. MOREY, M.S.

The recent introduction of *DSM-III* has stimulated new debate among mental health professionals. Schact and Nathan (1), for example, expressed the concern that psychology as a profession was not much involved in the development of this manual. As a result, one might suspect that psychologists would see *DSM-III* as less valid than would psychiatrists.

Other studies, e.g., that of Seegars and Miller (2), have demonstrated that professionals from different mental health disciplines conceptualize diagnostic categories and the corresponding symptomatology in differing ways. From a theoretical standpoint, this is almost certainly true. However, *DSM-III* eschews theory to a large extent and relies heavily on the identification of specific symptoms and behavioral signs in making a diagnosis. Once the clinician has made this identification the rest of the diagnostic process is more or less automatic. Thus, an investigation of professional differences might best be done at the symptom level.

This study attempted to assess whether psychologists and psychiatrists differ in their perception of the validity of *DSM-III* defined signs and symptoms. If one assumes extreme professional differences in diagnosis, the expectation would be that psychologists would see symptoms that were based on psychological research as highly valuable (e.g., "constructional difficulty—inability to assemble blocks" as diagnostic of dementia) and that psychiatrists would rely on traditional medical model symptoms. Although examining these possible differences was the primary focus of this study, another important clinician variable was also examined. This second variable, the level of experience of the diagnostician, has been proposed to be a salient factor in diagnostic studies (3).

Method

Participating in this experiment were 30 clinicians: 15 psychiatrists and 15 clinical psychologists. These clinicians ranged in level of experience from 1.5 years to 44 years (mean=13.6 years). Of the 30 clinicians, 6 (20%) were women. All clinicians worked in and around Gainesville, Fla., in many diverse settings. In total, 16 of the clinicians held full-time academic appointments in a teaching or Veterans Administration hospital, and 9 worked primarily in the community. The remaining 5 clinicians were psychiatry residents or psychology interns.

A card sort technique was used to obtain the clinicians' ratings. The stimuli were index cards with one symptom typed on the front. A symptom was defined as the smallest subunit of a *DSM-III* criterion that could be retained without losing its meaningfulness. Thus, a list of symptoms joined by an "or" was separated into individual symptoms. For instance, one criterion in the *DSM-III* definition of schizophrenia was defined as follows (criterion A-6): "Somatic, grandiose, religious, nihilistic or other delusions without persecutory or jealous content." In this study, that criterion was divided into 6 separate symptoms.

For the purposes of this study, three diagnoses were selected for intensive study: schizophrenia, mania, and dementia. In addition, symptoms were included from the personality disorder axis so as to present a less clear-cut diagnostic picture. In total, there were 47 schizophrenic symptoms, 20 dementia symptoms, 22 mania symptoms, and 15 personality disorder symptoms in the card sorting task.[1]

A high rate (94%) of all clinicians contacted agreed to participate in the study. At the time the study was undertaken *DSM-III* had not been officially put into use, and thus the clinicians were unfamiliar with the criteria from which the stimuli had been derived.

Each clinician was given a shuffled stack of index cards and asked to sort the cards into five piles. They were to arrange the cards from the lowest (value=1) to the highest (value=5) information/importance of a symptom they would use in making a particular diagnosis. The clinician was not told the diagnoses in advance. The categories used were (in random order) mania, schizophrenia, and dementia resulting from an organic brain syndrome. Hence, each symptom was rated on three disorders.

Results

To assure that profession and experience were not confounded factors, a test was performed to determine if the mean level of experience was different between the psychologists (13.70 years) and the psychiatrists (13.47 years). This difference was not significant ($t=.06$, $df=28$, $p>.95$).

An analysis of variance was then performed for each

[1]A complete list of all symptoms is available from the author.

symptom rating using profession and years of experience as main effects and including the interaction term in the model. This resulted in a total of 314 analyses because all symptoms were rated on three diagnoses. A multivariate analysis of variance would have been desirable, but this was contraindicated by the large number of variables relative to the number of subjects. By examining the number of significant analyses we may obtain an idea of the effect of these clinician variables. Of the 314 analyses, only 18 analyses (5.7%) were significant at the $\alpha=.05$ level, and 2 analyses (0.6%) were significant at the .01 level. These numbers are essentially the number of analyses that would be expected to be significant by chance alone. Because in general all the clinicians rated the symptoms similarly (median correlation between clinician=.55), this finding cannot be an artifact of entirely unreliable data. On the whole, the clinician variables of profession and experience, as well as their interaction, were not significant factors in the rating of symptom validity.

Discussion

It is interesting that neither the profession nor the experience of a diagnostician had any effect on his or her perception of *DSM-III* symptom importance. Primarily, these results indicate that when psychiatrists and psychologists operate at a very specific level of evaluation, any global biases in their perspectives do not seem to have an effect. Thus, *DSM-III* may well have been effective in removing a possible source of diagnostic unreliability because it mandates decisions at this specific level. In addition, these findings indicate that the study of the clinician in diagnostic research has utility, at least when considering specific symptom information, because at this level theoretical bias tends to be minimized.

This study presents a new methodology for diagnostic research that might be very powerful if it were expanded beyond the somewhat limited sample of this study. Perhaps when the official diagnostic system is revised again, this model of studying the clinician's use of specific information might be applied.

Propranolol, Chlorpromazine, and Tardive Dyskinesia

SIR: The exciting results reported in "Low-Dose Propranolol in Tardive Dyskinesia" (April 1980 issue) by Norman M. Bacher, M.D., and Harvey A. Lewis, M.D., warrant further investigation. However, we wish to alert the authors that chlorpromazine was recently demonstrated to significantly increase plasma levels and bioavailability of propranolol in man (1). Chlorpromazine (50 mg given orally t.i.d. for 5 days) significantly reduced intrinsic clearance and elevated steady-state plasma levels of propranolol (80 mg given orally t.i.d. for 3 days). There were no associated changes in liver blood flow, volume of distribution, half-time, or plasma binding of propranolol, and the investigators concluded that chlorpromazine inhibits the metabolism of propranolol.

If this interaction occurs at an enzymatic level, it is also possible that propranolol, by competing with chlorpromazine for enzymatic degradation, might increase plasma levels and bioavailability of chlorpromazine and other neuroleptics. It is well known that symptoms of tardive dyskinesia may be temporarily improved by increasing neuroleptic dosage, but that the symptoms may eventually worsen. Consequently, it will be important to monitor plasma neuroleptic levels in patients receiving combined neuroleptic-propranolol regimens, and to be aware that the combined administration may increase the toxicity of both agents.

Drs. Bacher and Lewis Reply

SIR: Dr. Risch and associates have provided important new information, postulating a possible mechanism of action of combined propranolol-neuroleptic in tardive dyskinesia. Propranolol may increase neuroleptic levels, thereby suppressing tardive dyskinesia symptomatology, and Dr. Risch and associates issue a caution regarding toxicity. They point out the importance of monitoring plasma neuroleptic levels in future studies using combined medications.

We are continuing trials with low-dose propranolol in outpatients with tardive dyskinesia who are receiving neuroleptics. In two resistant cases we have increased the propranolol dose to 80 mg/day, without side effects. Many of our psychiatric outpatients are seen for concurrent medical problems and receive neuroleptics combined with much higher propranolol dosages. We have not seen significant side effects or toxicity in these patients.

One of our original patients, who showed improvement in tardive dyskinesia with low-dose propranolol, was not receiving neuroleptics; this suggests that the improvement may have been caused by propranolol alone. We agree that further investigation is warranted.

More on Suicide and Women Physicians

SIR: In "Suicide Among U.S. Women Physicians" (May 1979 issue) Ferris N. Pitts, Jr., M.D., and associates calculated the morbid risk for primary affective disorder in women physicians as 65.2%. This resembles a claim made by Craig and Pitts (1) more than 10 years ago. It is based on Pitts and Winokur's conclusions that all suicides are the result of primary affective disorder and that 10% of the deaths of women with primary affective disorder result from suicide. Aside from the issue of the first conclusion's validity, we question the applicability of the second conclusion to this situation. The figure of 10% is based on a sample of psychiatric patients from the general population. Women physicians constitute a subgroup that differs considerably from the total group of women diagnosed as having primary affective disorder. For example, socioeconomic status and intelligence probably differ between the two groups, and these variables may be associated with psychological factors significant to suicidal risk, such as impulse control and variety of coping mechanisms. Within a subgroup that was homogeneous with respect to these variables and diagnosed as having primary affective disorder, the suicide rate might be quite different from that of the larger group of patients with primary affective disorder. As the authors suggested, the only valid

way of determining the rate of primary affective disorder among women physicians would be through structured interview studies. Until these are reported, claims that two-thirds of women physicians suffer from primary affective disorder can only be viewed as highly questionable.

Women physicians have chosen to pursue professional careers in an area that has been traditionally male dominated. These women may not display some of the as yet unidentified aspects of psychological functioning that have served in the past to render women less vulnerable to suicide than their male contemporaries. With this possibility in mind, it is striking to note that Dr. Pitts and associates reported no statistically significant difference between the suicide rates of men and women physicians.

Suicide research would benefit greatly from an understanding of the factors underlying differences in suicide rates observed between men and women and between physicians and nonphysicians.

Migraine and Schizophrenia

SIR: It is our clinical impression that patients with chronic schizophrenic illness do not suffer from migraine headaches. Vascular headaches occur in 4% to 15% of the population, and recently prevalence of migraine was reported at 7.3% in a general adult sample. The incidence of schizophrenia is generally estimated at 0.8% to 1%. On epidemiologic grounds, one would expect to occasionally see some schizophrenic patients with migraine. However, in our psychiatric clinics and our biofeedback laboratory we have yet to see a migraine headache sufferer with chronic schizophrenia, or a patient with schizophrenia who also has migraine headaches.

If this observation of negative correlation between chronic schizophrenia and migraine turns out to be valid, it might have heuristic value. Both disorders, migraine and schizophrenia, occur in families, suggesting the possibility of a genetic component. Abnormal monoamine oxidase functioning has been reported in both disorders (1, 2). Both conditions show some response to propranolol, a beta-blocker (3, 4). Most psychiatrists would agree that chlorpromazine, a phenothiazine antipsychotic drug, is useful in the treatment of schizophrenic illness. Chlorpromazine has been reported to be dramatically effective in prophylaxis against severe paroxysmal vascular headaches that are refractory to other measures. Methysergide, a 5-hydroxytryptamine receptor blocker, is useful in migraine prophylaxis, but reportedly aggravates symptoms in some chronic schizophrenics.

This may be looking for the proverbial needle in the haystack, but biological psychiatry has recently produced some interesting insights into the complexity of the schizophrenic syndrome. Perhaps an alteration of biogenic amines protects patients with schizophrenia from migraine, a quite common disorder. Meltzer (5) suggests that there could be a significant relationship between indoleamine and the dopamine hypotheses of schizophrenia.

We would be interested in the comments of *Journal* readers on this subject, especially clinicians who run large migraine clinics.

The Outlook for Children of Manic-Depressive Patients

SIR: In "Children at Risk for Manic-Depressive Illness: Possible Predictors" (September 1979 issue) Clarice J. Kestenbaum, M.D., theorized that the children of bipolar manic-depressive patients may exhibit symptomatology which does not take the form of classical primary affective disorder but reflects the "fundamental genetic liability" to the condition. This is an attractive hypothesis. Dr. Kestenbaum cited the report of McKnew and associates (1) and alluded to others (2) as support. However, after having interviewed or supervised the interviewing of 67 offspring of patients with bipolar manic-depression, I question Dr. Kestenbaum's proposition.

I originally intended to focus on the children of bipolar patients in the type of prospective study Dr. Kestenbaum advocated. After interviewing 19 such children (6-15 years old), I found that the psychopathology of the 11 I judged to be disturbed was not distinctive in any way from that of the rest of the patients in my clinical practice and did not appear to be definite primary affective disorder.

I shifted the focus of the study to the older offspring (16 years and older) who had entered the age of risk to primary affective disorder and for whom there were reliable primary affective disorder criteria. Of the 48 interviewed to date, representing the offspring of 16 bipolar patients (2 had committed suicide and 1 refused to be interviewed), 18 met the Research Diagnostic Criteria (3) for primary affective disorder and 8 for other psychiatric disorders. The mean age of the offspring was 27 years and the mean age of primary affective disorder onset was 16 years (range, 10-31 years).

Compared with their well siblings, those offspring with primary affective disorder did not show a decline in their achievement before the onset of their illness nor were they more likely to have previously come to the attention of psychiatrists or other mental health workers.

These results are in accord with those reviewed elsewhere (2). Thus, in answer to Dr. Kestenbaum's question, "What are the indications that a child with behavior disorder, hyperactivity, or neurotic symptoms may be at risk for future

manic-depressive illness, may be exhibiting a manic-depressive variant, or that the symptoms are evidence of manic-depressive illness per se?" one may reply that although the children of bipolar patients may be at enhanced risk to psychopathology and to school-related problems, unless the condition is clearly concordant with primary affective disorder there is no substantial evidence it will evolve into frank primary affective disorder.

Nevertheless, living with a parent suffering from bipolar manic-depression can in itself be a traumatic experience and may explain some of the symptomatology that younger offspring exhibit, either as a reaction to, or an identification with, the sick parent.

B. WATERS, M.B.B.S., DIP. PSYCH.
Ottawa, Ont., Canada

Dr. Kestenbaum Replies

SIR: Dr. Waters has observed that in his clinical evaluation of the offspring of bipolar manic-depressive patients, only 11 of the 19 children interviewed (aged 6–15 years) were psychiatrically disturbed; the type of psychopathology, moreover, was not found to be distinctive in any way from that of other patients in his clinical practice. My intention has been to search for possible biological markers before the appearance of clinical symptoms, which are usually manifest by late adolescence in those destined to have a manic-depressive disorder. Thus I noted the finding that psychological test scores of children of bipolar probands had, to a significant degree, a substantial verbal-performance WISC differential in the direction of lowered performance scores. I agree that the clinical symptomatology itself was not distinctive, but coupled with positive family history and lowered performance scores, it suggested vulnerability to a manic-depressive disorder in adult life.

I have noticed that many children of manic-depressive patients, even when exhibiting some psychopathology, were not given psychological tests. Often these tests were omitted because the children were bright, verbal, and functioning well at school. A double-blind study currently under way should help to clarify some of these issues. I certainly agree with Dr. Waters about the traumatic effects of living with manic-depressive parents; psychopathological reactions in the face of intrafamilial stress cannot be ignored.

Empirical Data and Insanity Acquittals

SIR: Henry J. Steadman, M.D.'s call for empirical data to support legislative and administrative decisions in "Insanity Acquittal in New York State, 1965–1978" (March 1980 issue) deserves hearty support. Dr. Steadman showed that data from different states can add to our general understanding of the effects of different legal procedures. However, data derived only from mental health files, correctional admissions, or the judicial system cannot tell all that is needed to trace the operation of a statute.

Comparing insanity acquittals with corrections admissions on the basis of sex and ethnic background could enhance the meaning of other cross-departmental comparisons within the same state. The value of data coordinated among several governmental departments may be further illustrated by questions that arise from review of Dr. Steadman's tables.

For data arranged by type of crime, the disparity between the relative frequency of offense and insanity acquittals is striking. Burglary, a frequent offense, leads to only 2.5% (1965–1976) or 7.3% (1976–1978) of insanity acquittals, while murder, a far less frequent offense, leads to 53.4% or 43.5% of insanity acquittals. New York criminal justice data on the frequency of different offenses, frequency of prosecutions, and frequency of insanity pleas, considered with Dr. Steadman's data, could tremendously enhance efforts to trace the workings of insanity defense statutes.

Cross-departmental data would be indispensible in objectively analyzing whether the higher rate of insanity acquittals for murder results more from a murderer's psychological condition (compared with a burglar's psychological condition), from underlying assumptions by trial participants (murder is insane, but burglary isn't), or from trial participants' contemplation of the severity of punishment should the defendant be found guilty. Judicial system information about the prevalence of both pleas and acquittals, arranged by judicial district, by court, by prosecutors, by defense attorneys, and even by expert witnesses could also help in analyzing the operation of such laws and local ground rules.

Dr. Steadman is more aware than most of us of the administrative difficulties in attempting to collect systematic and comparable data from different state departments. However, if his call for more empirical foundations for policy decisions is to be adequately implemented, some central authority must mandate funding for studies that cross departmental lines within the same state.

A Sterile Theory of Depression?

SIR: Only with some trepidation would I criticize the work of Dr. Aaron T. Beck, who has contributed so much to our knowledge of depression; yet it would be a disservice to him to withhold a candid response. Despite the success of his cognitive therapy, Dr. Beck's view of depression as a primary thought disorder is fallacious as discussed in *Cognitive Therapy and the Emotional Disorders* (reviewed by Mardi J Horowitz, M.D., December 1979 issue).

In response to Drs. Kovacs and Beck's "Maladaptive Cognitive Structures in Depression" (May 1978 issue) Mark T. Schreiber, M.D., pointed out that "the authors interpret in a causative role what others have considered to be merely the symptoms or effects of depression" (1). Drs. Kovacs and Beck replied "that the cognitive model has a greater explanatory power of the phenomena of depression than other

psychological models presented to date. The model, however, does not address the ultimate etiology or cause of unipolar depression, which may encompass hereditary predisposition, faulty learning, brain damage, biochemical abnormalities, or any combination thereof" (2).

I agree that current theories of depression are limited. However, regardless of ultimate etiology or cause, the primary level of psychopathology of depression is affective, not intellectual, although an intellectual approach in therapy may be successful. Unfortunately, the clinical sciences have a relatively minimal effect upon unipolar depression given the incidence of this syndrome in our society today. We urgently need a fresh approach to this ubiquitous problem. Perhaps something as simple as viewing depression as the absence of pleasure might point us in a more positive direction. I do not mean to underestimate the complexity of the problem but it does seem that current psychological theories of depression have been sterile.

Apartheid and Psychiatry

SIR: Distance has shielded me for almost 18 years from having to grapple mentally with the complex political situation in South Africa. However, the stirring Report of the Committee to Visit South Africa (November 1979 issue) demands that from my knowledge of my native land until 1962 I either agree with the observations, repudiate them, or comment constructively.

Unfettered political comment in South Africa became increasingly difficult after 1948, when the current governing party first gained control on the strength of their apartheid policies. The battle lines were drawn and the crossfire between white Afrikaner Christian nationalism and black African nationalism became a real threat to those who could not comfortably identify with either group. For those like myself, progressively extruded by a process which made little allowance for compromise or for shades of political difference, the conscious choice to leave became more attractive. After the 1960 Sharpeville event, the emigration of those who felt disenfranchized gained momentum, and the meager ranks of South African psychiatrists became more meager still.

I believe I have some understanding of the conflict confronting my South African colleagues who attempt to present South African psychiatry in a favorable light. I personally have no knowledge of the Smith Mitchell operations, but am familiar with the "bachelor compounds" for the black mine laborers and completed part of my psychiatric training in both Weskoppies and Sterkfontein, two of the mental hospitals visited by the committee. In 1977, when the accusations were first levelled at South African psychiatry for incarcerating political prisoners in mental hospitals and abusing ECT and psychotropic drugs for political purposes, I knew them to be absurd, and I knew from my contact with former colleagues that no major shifts in mental hospital policy had occurred since my departure in 1962. The APA committee's findings confirmed that view. The APA committee also confirmed that the psychiatrists and the professional staff they interviewed were hospitable, gracious, and candid. They were not evil people.

South Africa is unique in its intense contrasts and contradictions. Black domestic servants daily touch on the most intimate aspects of their white employers' lives, but genuinely share few experiences. The committee aptly described this paradox: "We have tried to be as objective as we could be, as foreigners confronting for the first time a country whose astonishing physical beauty and hospitable people were in such stark contrast to the ugliness of its apartheid system."

The South African ruling party has been consistently returned to power by the white electorate for more than 30 years. It is driven by the long-standing Afrikaner fear of being overwhelmed not only by blacks but also by whites of any different ethnic or religious background. Despite the opportunity to create a more comfortable racial balance by encouraging white immigration, when this governing party gained power in 1948 it immediately restricted the flow of immigrants from Europe. Having lost opportunities to change gradually, many members of the governing party have become locked even more rigidly into their apartheid posture, believing any shift that increases the financial or political power of blacks will hasten black majority rule.

Most of the APA committee's observations probably reflect or approximate the true state of affairs. Apart from some exceptional facilities, hospitals for blacks provide less comfort and fewer amenities. If the medical records the committee inspected reflected no physical examination before transfer from the mental hospital to the Smith Mitchell facilities, one must assume that no such examination was done. This applied in larger measure to the black patients, yet the records of some white patients similarly lacked any reference to a physical examination. An inspection of U.S. state hospitals and the medical plight of our deinstitutionalized mentally ill would give us little to crow about, but the discrimination here is against the mentally ill, not on the basis of race.

The APA committee roundly condemned the policies of apartheid and the inferior care provided to black psychiatric patients. From their observations it would be difficult to draw other conclusions. However, I find myself unable to agree entirely that the committee's findings substantiated the allegations of social and political abuse of psychiatry. The absence of any evidence of the punitive use of psychiatric incarceration and treatment, of evil intent on the part of the caretakers, and the total disregard for political party affiliations among the mental health professionals characterize the system as vastly different from that which exists in the Soviet Union. The committee's criticism focuses essentially on the fact that the policy of apartheid has infiltrated deeply into every aspect of living, including psychiatric care. The quarrel is therefore with the official policy of apartheid, not with psychiatry or its practitioners who, sorely depleted in ranks, battle against great odds to provide what care they can in the best tradition of medicine.

The Biochemistry of Panic and Depression

SIR: In "Mitral Valve Prolapse Syndrome in Agoraphobic Patients" (April 1980 issue) Jerry Kantor, M.D., and associates described the high rate of mitral valve prolapse syndrome (MVP) in agoraphobic patients. Like these authors and other clinicians, I have noted this in my patients and would like to comment on pharmacotherapy. Of a group of 5 agoraphobic patients with MVP (diagnosed by auscultation and/or echocardiography), 3 responded to imipramine and 2 to phenelzine after an unsuccessful trial on tricyclics. In all instances the drug response occurred within 1 week after initiation of an appropriate dose of medication. Dr. Kantor and associates suggested a feedback loop in this syndrome, partially dependent on the hyperadrenergic state demonstrated by Boudoulas and associates (1). This feedback loop is antithetical to a therapeutic tricyclic or MAOI response if one is an advocate of the catecholamine hypothesis. If one does not "buy" the latter paradigm, the idea of an antidepressant drug inhibiting a hyperadrenergic state poses some fascinating possibilities about the biochemistry of panic, depression, and the mechanism of action of antidepressant medication. How intimate is the relationship between panic and depression? Do both include a hyperadrenergic state? Do antidepressants exert a direct antiadrenergic effect?

Failures of the Asylum or of Community Treatment?

SIR: In *The Death of the Asylum: A Critical Study of State Hospital Management, Services, and Care* (reviewed by Robert L. Okin, M.D., January 1980 issue) John A. Talbott, M.D., wrote, "State hospitals as they are currently constituted do not work, seem designed not to work, and have never worked."

I got the book to see for myself the evidence for this statement. I found a thorough exposition of why mental hospitals should not work and seem designed not to work. They are remote and big, managed by crises instead of by plan. They are over-regulated, buried in paperwork, have poor press, poor leadership, and are beset by legal and political interference. The staff is untrained, employee incentive is low, patients are lower class, budgets are insufficient, and the public and legislature are indifferent.

However, I found no evidence in the book of a scientific or research nature to prove that mental hospitals do indeed not work. In the long life of a public mental hospital chronic stayers and frequent repeaters accumulate, but there are also thousands who pass through who are never seen again. There is also the question of what the patients who make up the chronic population would be doing, if they survived at all, in the absence of the asylum. During the 1960s it became a truism that mental hospitals created all those chronic patients through mechanisms called dehumanization and institutionalization; this remains a truism in the minds of many. One of the problems that has beset asylums over the years is lack of funding for outcome research (although anthropologists and sociologists have come from academia to spend a few months looking at the cross-sectional picture). As far as I can ascertain there is relatively little research evidence to prove or disprove a thesis about whether asylums work.

Fort Logan Mental Health Center, one of the outstanding public mental health facilities in the 1960s, was designed to avoid the effects of institutionalization. Kraft and associates (1) documented the accumulation of hardcore, long-stay patients at Fort Logan after 4½ years of operation. They found the diagnosis of these long-stay patients to be "the old familiar one of chronic schizophrenia."

Dr. Talbott mentioned that the state hospital population decreased from a high of 558,992 in 1955 to 193,436 in 1976. This was largely due, Dr. Talbott implied, to an increased number of inmates in other kinds of institutions. No doubt there is an irreducible basic population of institutional dependents, but during the years 1955 to 1976 millions entered and left the mental hospital system, some never to return. Why are those who do return considered failures of the asylum rather than failures of community treatment?

Intrapsychic Structural Effects of Psychiatric Research

SIR: In "Intrapsychic Structural Effects of Psychiatric Research" (December 1979 issue) Samuel G. Siris, M.D., and associates presented a stimulating, humane approach to some major issues about inpatient psychiatric research. Although I am in almost complete agreement with them (1), I noticed several points that warrant further discussion.

First, I thought that the authors tended to switch back and forth between the use of a phenomenologic model (capacity for delay) and the use of a psychoanalytic approach or model (relationship with the superego). I found the article to be particularly interesting when the authors concentrated on their observations and on the clinical vignettes, e.g., the patient who interpreted blood drawing as an act of rape. Did the authors feel that discussion of structural theory and superego constructs was needed to make their major points? Why include the additional philosophical/structural constructs?

Second, the concluding paragraph stated that "many aspects of the research may well be adopted into the patients' reintegrating structures," implying that this may well affect therapeutic outcome. It seems that such experiences mainly affect patients' behavior in the hospital, which is important for day-to-day management and for the building of the therapeutic alliance. To the extent that such alliance building is important and may affect outcome, the authors may be correct. Yet, outcome and psychic reintegration are complex issues. Without more convincing evidence on either issue, Dr. Siris and associates' more far reaching arguments are fundamentally unsupported. In my experience, these research issues are of notable but minor importance and are almost always "washed out" by such factors as individual medication response, family issues, and the availability and funding of adequate follow-up treatment. I am not convinced that the patients' intrapsychic structures and outcome are as strongly affected as the authors implied.

Finally, patient-research subjects must be treated humanely and fairly. It is sad that these patients are sometimes treated as research tokens. Although academic pressure was not specifically discussed in the article, it may be an important factor contravening the adoption of the procedures that Dr. Siris and associates recommend.

DAVID L. BRAFF, M.D.
San Diego, Calif.

Dr. Siris and Associates Reply

SIR: We appreciate Dr. Braff and associates' contribution to the literature on the interactions between inpatient care and psychiatric research, and his thoughtful comments on our article. We are happy to take this opportunity to rectify some misunderstandings that our article may have engendered.

We regret if we confused readers with our descriptive presentation of clinical phenomenology within the conceptual framework of the psychoanalytic "structural" theory. We observed that this model of psychic functioning was quite valuable in understanding interactions between the reevolving organizational structure of patients' minds and the organizational structure of the ongoing research. We intended no phenomenological model. Rather our intention was to present empirically observed phenomena within the structural model. In this, for example, "capacity for delay," as an executive mental operation, is an ego function (1). Similarly, "superego" is a set of executive mental operations constituting a related part of the psychic structure. We are stimulated by Dr. Braff's implication that other models of the mind may provide a fruitful conceptual background for understanding the impact of constellations of external organization, such as research, on the human mind. We found that the psychoanalytic structural model of the mind was particularly felicitous for this.

In his second point, Dr. Braff generously extended the therapeutic impact of the phenomenon we described to the point of comparison with medication response, provision of follow-up care, and the understanding of family interactions. It certainly was not our intention to suggest that the influence of the structure of research on manifest psychiatric symptomatology was comparable quantitatively to those potent clinic modalities. Properly executed research is not supposed to be a clinical modality; it is supposed to be research. Nevertheless, the structure of aspects of research functioning did seem to have a clear influence on the structure of aspects of patients' psychic functioning. This was a more qualitative observation, which we found instructive and which did suggest to us that a process was indeed afoot that could potentially affect patients' adaptive capacities one way or the other.

In respect to Dr. Braff's third point, we could not agree more that humane and fair treatment of patient-research subjects is intrinsically right. Although it was not central to the specific thesis of our paper, we certainly join him in his concern that academic pressures may work to the detriment of the best patient care. Since these pressures are, unfortunately, natural and to a certain extent unavoidable, the judgment and expertise of every researcher stand to be challenged.

Positive Experiences in Bipolar Patients

SIR: As reported in "Clouds and Silver Linings: Positive Experiences Associated with Primary Affective Disorders" (February 1980 issue) Kay R. Jamison, Ph.D., and associates asked groups of euthymic or mildly depressed unipolar and bipolar patients if their mood swings had affected such personality characteristics as overall psychological sensitivity, sexual enjoyment, productivity, creativity, and social outgoingness and ease. Although the two groups did not differ on the overall psychological sensitivity variable, bipolar patients reported significantly more positive experiences related to the effect of their mood swings on personality and productivity than unipolar patients did. The only apparent explanation offered for these group differences concerns the scales used to assess the bipolar patients during periods of hypomania and mania. Since these scales were designed to assess positive rather than negative attributes of affective illness, a possible positive response bias in the bipolar group may have existed.

Our research with depressed patients suggests that adaptive bipolar defense mechanisms provide an additional explanation for the results we obtained. First social desirability (e.g., subscribing to those characteristics that are desirable in our society so as to appear in the most favorable light) and depression are significantly related ($r=-.65$) in

bipolar depressed groups but are not related (r=.07) in unipolar groups (1). In contrast, individuals with high anxiety (e.g., the unipolar compared with the bipolar group [2]), seem to endorse socially undesirable response sets. Behaviorally rated compared with self-reported assessments of unipolar and bipolar groups do not elicit significantly different psychological characteristics (3). Second, bipolar defenses against the stress of depression appear to be considerably more adaptive than those of the unipolar group to the extent that self-reports of dysphoria and anxiety are attenuated in the former group (4). Thus bipolar groups are frequently described as "normal" when, in fact, this designation should be strictly limited to comparisons with unipolar groups. Third, bipolar depressed groups give evidence of their adaptive defenses on tests of self-report through the mechanism of denial (5), a defense long associated with hypomania. It can be inferred, then, that the more successful adaptation to depression in bipolar depressed patients compared with unipolar depressed patients presents a more positive, "normal," and healthy psychological picture.

Tips from a Chart Browser

SIR: In this modern era, when we discharge psychiatric patients weeks or even days after they have been admitted and worked up, there is a need to assist trainees of all helping professions in writing up rapid case histories. To wit, I offer the following "tips"—apologizing for a term more redolent of off-track betting than of the medical model, although our passion for follow-up studies often makes us more interested in how our patients fare at the end of the race than how they present themselves at the starting-post of our institutions.

The following charting rules of thumb can be applied to all inpatients and to the vast majority of outpatients in a hospital setting:

1. You can always say that the patient is "suffering from low self-esteem." You will be wearing your more analytic hat, however, if you factor out the most successful aspect of your patient's personality functioning and then say that "this area of apparent strength is used to cover over issues of low self-esteem." This sort of statement is 100% safe to make in all cases—almost as safe, in fact, as saying that a patient's condition has "an underlying affective component." This is, after all, an age of intense affects.

2. Every patient should be said to have "constitutional factors contributing to (or predisposing to) the development of" an acute psychotic break, a major depression, et cetera.

3. Attribute your patient's peculiar inability to weather the stresses of life that assault us all either to (but never to both) "deprivation" or "overindulgence," preferably some time during the first two years of life. This follows a long psychiatric tradition of making use of opposites, albeit one at a time, to explain whatever phenomena one happens to be observing.

4. All patients are "ambivalent." Have you ever met anyone, your own analyst included, who didn't manifest "unconscious conflicts," especially around "sexuality and aggression"?

5. If the patient hates all the staff on the unit but likes you, then he is "capable of good object relations, if given the opportunity for a one-to-one relationship." If he likes everybody else but hates you, then he is clearly "splitting." Similarly, if you like the patient but hate your fellow staff, you can blame your patient's regressions on "tensions among staff" that your sensitive patient is alertly "responding to," and wow everyone by referring to these as "Stanton-Schwartz phenomena."

6. In the prognosis section of your case history be sure to make some statement implying that "the prognosis is guarded" if your miraculous treatment plan cannot be established.

7. If at all possible, look for and find: congenital stigmata, records of a low Apgar, soft neurological signs, abnormal reflexes, or a really loaded family psychiatric history. If you can't find these, call in anyone from a neurologist to a geneticist so he or she can find them.

8. For God's (and Bob Spitzer's) sake, never use or refer to or even dream about any diagnostic nomenclature other than the litany, *DSM-III*.

Now hop to it and catch up on that backload of charts you've been putting off for weeks; there's really nothing to it, once you've been around.

White Plains, N.Y.

Telephone Contact and Questionnaire Response

SIR: I am writing in response to Alvin A Rosenfeld, M.D., and associates' request (1) for reports of experience with a questionnaire respondent recruitment technique similar to the one they used in their study of Palo Alto families. Dr. Rosenfield and associates telephoned potential respondents to explain the purpose and design of their study before mailing questionnaires. This step increased their response rate greatly over that which is usually reported for mail surveys.

Last year I used a similar method with similar good results. I solicited the participation of 117 clinical psychology graduate students for the first part of a longitudinal study of professional development. Sixty-three were contacted by telephone; the other 54 were sent letters explaining the project with postcards to be mailed back if they were willing to participate. Ninety-eight percent of the graduate students contacted by telephone agreed to participate; 74% of them returned the questionnaires. Fifty-two percent of the graduate students contacted by mail agreed to participate; 79% of them returned the questionnaires. In Dr. Rosenfield and as-

sociates' study 97% of those contacted by telephone agreed to participate, and 86% of them returned the questionnaires.

The percentage of those agreeing to participate when contacted by telephone is virtually identical to the figure reported by Dr. Rosenfield and associates; a far smaller percentage of those contacted by mail were willing to fill out the questionnaire. However, once the decision to participate was made, those initially contacted by mail and by phone returned completed questionnaires at almost the same rate. This suggests that the crucial step in recruitment for such studies is securing the respondent's commitment to complete the questionnaire. Telephone contact is more effective in eliciting this initial commitment, perhaps because it allows the potential participant to ask questions and resolve any doubts he or she may have about the project. Telephone conversations also set up a quasipersonal relationship between researcher and respondent that makes saying no difficult.

Correction

On page 849 of "Haloperidol Excretion in Human Milk" by Ronald B. Stewart, M.S., Barry Karas, and Philip K. Springer, M.D., in the July 1980 issue, the fourth sentence of the last paragraph should read, ". . . an infant could receive a maximum of 0.0075 mg/day of haloperidol."

BOOK FORUM

NANCY C. ANDREASEN, M.D., EDITOR

The Borderline Syndrome: Constitution, Personality, and Adaptation, *by Michael H. Stone, M.D. New York, N.Y., McGraw-Hill Book Co., 1980, 530 pp., $27.50.*

During the past decade many American psychiatrists have shown considerable interest in the group of disorders subsumed under the borderline rubric. Although competing theoretical formulations abound on the subject, very few empirical studies have been conducted. Some of these formulations, particularly those in the tradition of Melanie Klein, are not intelligible to many nonanalytical clinicians. Further, as Perry and Klerman (1) have cautioned, the concept is being used somewhat indiscriminately for an increasing number of heterogeneous patient populations. Neo-Kraepelinian psychiatrists have generally voiced dissatisfaction with the concept, which they find too nebulous for formal diagnostic purposes. Many dynamically oriented psychiatrists, on the other hand, point to the inherent clinical utility of a broad concept that identifies patients who are borderline in their suitability for psychoanalytic treatment. The views of the dynamic camp have been expressed more flamboyantly, but criticism by the neo-Kraepelinian camp has also sporadically appeared. The split of American psychiatrists on the subject of borderline patients is perhaps best portrayed by the November 1978 issue of the *Journal,* in which the lead article by Shapiro was devoted to an extensive theoretical review of the developmental psychopathology of these patients and the last article was a scathing critique of the concept by Rich.

Dr. Michael Stone has written a critical appraisal of the borderline concept that should satisfy both camps. Indeed, this is a unique book. The author, an analytically trained clinician, attempts to validate a concept developed largely within the analytical tradition by recourse to methods developed by descriptive and biological psychiatry. Because of this methodological advance, Dr. Stone's monograph can be considered a landmark in American psychiatry.

Beginning with Stern, analytical writers were concerned with the early identification of patients who were "falling apart on the couch." Within a linear dynamic logic of decompensation into psychosis, early discussions of borderline patients almost invariably referred to borderline schizophrenia (chapter 1). This was in line with the broader Bleulerian concept of schizophrenia. Eventually, however, Knight and others (table 7-1, pp. 163–164) foresaw the greater affinity of these disorders to the affective psychoses. The major clinical accomplishment of Dr. Stone's work is the convincing argument that psychostructurally defined borderline patients (according to Kernberg's schema) are on the genetic border of the affective rather than the schizophrenic disorders. By undertaking an extensive investigation of morbidity risks for affective and schizophrenic disorders in first-degree biological relatives of borderline probands (chapter 4), the author has shown a significant excess of affective but not of schizophrenic disorders.

Most previous workers have attempted to delineate the genesis of borderline psychopathology in developmental dynamic terms. Dr. Stone further traces this to its *literal* genetic origins:

> The suggestion of a hereditary factor is no new discovery. It was, if anything, taken for granted by the psychiatric and psychoanalytic communities until the second generation of psychoanalysts began to adopt a more linear and purely psychological model of causation. (p. 7)

In his critique of unidimensional models of character formation, Dr. Stone attempts to reformulate dynamic theories within the larger frame of psychiatry. He thereby renders an invaluable service to the discipline of psychoanalysis. Future contributions by the dynamic schools will be more meaningful when evaluated by the same canons of research methodology that psychiatry at large is finally adopting. Dr. Stone's monograph can serve as a touchstone toward such efforts because it is explicitly based on the premise that dynamic concepts—no matter how internally consistent—may eventually lose their heuristic value if not examined in the light of other approaches that can function as external validating criteria. For that matter, without susceptibility to such external validation, *all* psychiatric concepts are tentative at best.

The clinical popularity of borderline diagnoses in recent years has been disproportionate to their nosologic validity (1). Dynamic thinking on the characterological pathology may fascinate clinicians, but, unfortunately, it can also give them a sense of premature certainty about the origin and treatment of this diverse group of "primitive" personality disturbances. In defense of the clinician, it is only fair to mention that until recently borderline cases often could not be classified within traditional diagnostic categories.

Now that operational criteria—largely based on Gunderson's work—have been proposed by *DSM-III,* it is feasible to follow up such cases for eventual nosological clarification. In his review of recent nosological approaches (chapters 8–10), Dr. Stone concludes that only a small minority of borderline patients fit into the schizotypal group (genetically on the border of the schizophrenias), while the majority constitute such early or "dilute" forms of affective disorder as dysthymia, cyclothymia, and bipolar II (genetically on the border with affective disorders). Furthermore, Stone's probands were at high risk for developing affective disorders—both depressive and manic decompensations—during psychoanalytic therapy (chapter 8).

Thus, both phenomenological and genetic approaches seem to converge in placing borderline patients on the bor-

der of affective illness. (Other evidence that has appeared since the publication of this book and that supports this conceptualization is early escape from dexamethasone suppression (2) and shortened REM latency (3) in many borderline patients examined with the use of these biological markers for affective disorders.) The other two conceptualizations offered by the author include conditions borderline to the genetic interphase between schizophrenic and affective illness and an intermediary character formation between neurosis and psychosis. The former viewpoint is at present only a hypothetical possibility because the nosological status of schizoaffective states themselves is unsettled at this time. The latter viewpoint is not acceptable by contemporary nosologic standards (e.g., *DSM-III*), which find no evidence for the existence of a unitary "neurosis" or a "psychosis."

As the schizotypal disorders and the heterogeneous group within the affective spectrum—including the related substance use disorders—are more clearly delineated, the term "borderline" itself may become unnecessary (4). The burden of proof for sustaining the use of borderline as a distinct personality operation (on axis II of *DSM-III*) rests with authors who claim a more or less specific developmental psychopathology *generic* for this heterogeneous group of disorders.

It would have been preferable to address the nosological and phenomenological issues (chapter 8) before the lengthy chapter on the genetics of affective and schizophrenic disorders, which are competently discussed but are abundantly available in other books. Furthermore, case material could have been introduced at appropriate junctures into the main text of the book, instead of being relegated to a terminal chapter. Redundancy could thereby have been avoided, resulting in a text two-thirds of the present size. Fortunately the author's concepts are condensed and illustrated through the medium of diagrams and tables, of which figure 8-9 is perhaps the best.

Despite minor shortcomings in form, this is a very readable book. It should be read, however, at multiple sittings. The author's elegant style assists in achieving conceptual clarity. Indeed, both descriptive and dynamic psychiatrists who may have been mystified by the plethora of publications on the subject will find this monograph both lucid and informative. This very clarification, which may eventually result in the nosologic demise of the borderline concept as is happening with the dual parent concepts of "neurosis" and "psychosis," could paradoxically prevent the book from becoming a classic!

Fin de Siècle Vienna: Politics and Culture, *by Carl E. Schorske. New York, N.Y., Alfred A. Knopf, 1980, 378 pp., $15.95.*

Books which are both heavy and light reading are a special breed indeed, but this book has both those qualities. It is an intensive exploration of the intellectual, social, and cultural life of Vienna at the turn of the century. It presents a convincing case that, much as tiny fifth-century Athens was the cradle of classical rationalism, *fin de siècle* Vienna was the source from which the tormented and irrational modern era was born. This book describes how that rather traumatic birth occurred. Its content is demanding; but its very richness and density also make it fascinating and exciting reading. New ideas and insights sparkle all through the book.

Its method is that of intellectual and social history, focusing on a small slice of time and exploring it in careful detail so that the grain and texture of the era become immediate and vivid. Schorske reconstructs the Vienna of Freud and his contemporaries as it existed during the final decades of the nineteenth century, showing how in one aspect of life after another an old order of tradition and discipline died and a new one emerged that emphasized individuality and rebellion. Schorske describes *fin de siècle* Vienna as perhaps the last city in Europe to remain small enough for the intellectual elite to know one another well and to exchange and cross-fertilize one another's ideas. One senses the excitement that must have prevailed in this unique environment as revolutionary new ideas were presented in one field after another—in the art of Klimt, the psychology of Freud, and the music of Schoenberg.

The book contains seven chapters, several of which were published initially in historical journals and which received wide recognition and acclaim among Schorske's peers. The first chapter sets the theme of the book by arguing that the crucial characteristic of our modern era is our loss of a sense of history, our lack of a sense of continuity with our past, even our desire to destroy the world that our fathers created. But our fragmentation has not only been longitudinal and chronological; it has also been cross-sectional and spatial. The various intellectual disciplines have become so independent of one another that art, science, and politics no longer aspire to communicate with one another. The age of the synthesizers and universal geniuses is gone, broken apart by an era of analysis and specialization.

Subsequent chapters explore how these changes occurred in various fields. The second chapter examines two literary figures of late nineteenth-century Vienna, Hofmannsthal and Schnitzler, showing how they struggled with the problem of the loss of traditional liberal ideas and solved it by substituting psychological and aesthetic values. The third chapter explores the relationship between architecture and social change. It contains a fascinating description of the development of the Ringstrasse, showing how Viennese taste in public buildings and private apartments mirrored the changes that were occurring in social structure and values. The chapter is liberally illustrated with photographs of the buildings described. It makes one long to walk through the streets, look at the facades of buildings, and see and understand them with a perspective enormously enriched by Schorske's insightful descriptions of how they came into existence.

Subsequent chapters focus on politics, psychology, art, and music, weaving in new themes and ideas. The roots of anti-Semitism, Zionism, and demagoguery are described in

the careers of three politicians of the era: von Schönerer, Lueger, and Herzl. These themes are interwoven with a theme introduced earlier, the death of traditional liberal values. All these themes lead naturally into the career and personal crisis of Sigmund Freud, passed over for academic promotion because of his Jewishness, struggling with his own father's death and preoccupied with the subject of patricide, shocking his contemporaries with his revolutionary ideas about the importance of sexuality. The themes introduced by Freud's crisis move naturally into the artistic revolution created by Gustav Klimt, leader of the Secessionist School, which used his *nuda veritas* as its symbol, creator of a frankly provocative sensuousness in both subject and expression. Yet rebellion had its price, as Schorske points out:

> In "Watersnakes" (Plate II), the woman's sensuality both gains a new concreteness and becomes more threatening. . . . Klimt's women-as-snakes overwhelm the male not so much with the temptation of the Garden as with a sense of his inadequacy in the face of their seemingly inexhaustible capacity for carnal bliss. In his exploration of the erotic, Klimt banished the moral sense of sin that had plagued the righteous fathers. But in its place arose a fear of sex that haunted many of the sensitive sons.

The final chapters explore further the theme of the garden, a traditional symbol of both order and destruction of order through rebellion. These chapters return again to literature through the figures of Stifter and Hofmannsthal and to art through the figure of Kokoschka.

The book begins by viewing Ravel's *La Valse* as symbolic of the dissolution of traditional Vienna, for in it the ordered waltz movement disintegrates before one's ears. It concludes with the music of Schoenberg, who explored the themes of *Liebestod* and *Angst* in his content and who exploded traditional concepts of harmony in the dissonance of the 12-tone scale.

This book is a fine demonstration that synthesis can be achieved indeed in the Age of Analysis. It is beautifully written and illustrated. Its breadth is exciting. Its appeal is broad. Both Freudians and patricides will find something in it to enjoy and to admire.

Brief Mention

Medicine and Literature, *edited by Enid Rhodes Peschel. New York, N.Y., Neale Watson Academic Publications, 1980, 204 pp., $15.00.*

Medicine is sometimes called a healing art. Much to the dismay of humanistically oriented physicians, in recent years the artful and intuitive aspects of clinical practice have been minimized and the scientific aspects maximized. This book attempts to reunite medicine and the humanities by addressing the subject of literature and medicine.

It contains three types of essays. The first set deals with physician-writers such as Chekhov, Rabelais, William Carlos Williams, and Richard Selzer. The second set of essays examines doctors as portrayed in literature, looking at works by Flaubert, Camus, and Shakespeare. The third set of essays explores the experience of illness as portrayed in literature. Some of these essays are interesting, and some are rather dull. Nearly all are written by literary scholars who appear to have had little direct experience with the practice of medicine, a fact that sometimes gives the book a rather mandarin and esoteric quality.

Biological Aspects of Mental Disorder, *by Solomon H. Snyder, M.D. New York, N.Y., Oxford University Press, 1980, 253 pp., $13.95.*

The title of this book, written by one of psychiatry's most distinguished biological researchers, suggests that it will provide a summary of recent explorations in the biology of psychiatric disorders. In fact, however, the title is misleading. The book provides a relatively simple summary of the entire field of psychiatry, including diagnosis and classification, psychological and biochemical theories concerning etiology, and a variety of treatments including both psychotherapy and drug treatments. Neurochemistry and neuropharmacology, which one would expect to be major strengths in this book, are discussed only briefly, and neurophysiology is scarcely touched on. All types of mental illness are discussed, ranging from the major psychoses to the broad range of sexual disorders. Only the traditional neuroses and personality disorders are left out.

The book is directed at the level of the general reader or medical student. Its style is fresh and clear. Although Snyder is obviously trying hard to be comprehensive and to balance the biological with the psychological, one wishes that he had dealt more fully with his own area of strength and had not been so eclectic and overinclusive.

Experimental Design in Psychiatry: Research Methods for Clinical Practice, *by Walter W. Surwillo, Ph.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1980, 170 pp., $19.50.*

Psychiatrists who value rigorous and objective thinking sometimes find themselves handicapped or embarrassed by their lack of statistical skill. This book was written to remedy such handicaps. It is ostensibly addressed to psychiatrists at the residency level, and it would be quite suitable as a text for trainees who need to learn elementary to intermediate level statistics quickly. It would also be useful reading for psychiatrists who have completed their training and who are dismayed by their statistical illiteracy.

The book is clearly written and includes many illustrative examples that clarify the practical uses and potential abuses of particular statistical techniques. More than half the book is devoted to a discussion of such nonparametric techniques as chi-square, Fisher's exact test, the Mann-Whitney U Test, Friedman two-way analysis of variance (ANOVA), Kruskal-Wallis one-way ANOVA, and the Spearman rank coefficient of correlation. Parametric techniques such as the t test or the Pearson product-moment correlation or linear and multiple regression are also discussed more briefly. The author includes enough mathematics to make these techniques clear, but not so much as to overwhelm or intimidate

the reader. Discussions of experimental design, hypothesis testing, and the appropriateness of particular statistical techniques to various designs or methods of measurement are also included.

N.C.A.

The Uses of Psychiatry in the Law: A Clinical View of Forensic Psychiatry, *by Walter Bromberg. Westport, Conn., Quorum Books, 1979, 430 pp., $25.00.*

Walter Bromberg, M.D., a distinguished elder statesman in his field, has seen it all. One of the most moving passages in his new book, *The Uses of Psychiatry in the Law,* describes the conditions at Manhattan State Hospital on Ward's Island, New York, when Dr. Bromberg first started working there in 1928:

> The buildings that housed the "back wards," including the Inebriate Asylum built in 1854, appeared more antiquated as one moved away from the Administration Building. Here patients of all varieties—cases of dementia praecox, melancholias, manics—wiled away their years. The more disturbed were ordered to sit in straightback chairs, while the more compliant pushed a heavy wooden block across the hall for the obvious purpose of polishing an overpolished floor. There was no communication between patients and little with the nursing staff; some argued with imaginary foes outside the windows; some sat in Rodinesque immobility; some giggled foolishly. During the nonwork hours, the halls looked like an old Hogarth print. Occasionally, a crackling laugh issued from an upstairs window, or a grunt from a restrained manic broke the empty hum.
>
> In the morning, long lines of ragtag patients filed from the halls under attendant-guards, en route to menial jobs in the laundry or on the grounds. The men dressed in ill-fitting drab clothes, a cloth cap set at an idiotic angle, and talked and gesticulated to themselves. The women patients, in clumsy shoes and dun-colored dresses, giggled or mumbled to the morning air. Occasionally, one would depart from the file to emphasize a point to an imaginary persecutor or to lunge at a vexing enemy. The scene was dreary, hopeless, eternal.

Just as he has witnessed the enormous changes in the care of the mentally ill that have taken place since 1928, Dr. Bromberg has also witnessed, at first hand, almost the entire recent development of psychiatry and the law. The great strengths of his book are its comprehensiveness and his ability to illustrate his descriptions with so many examples from his long clinical experience, which includes being one of the medical experts to examine Jack Ruby (we are treated to a lengthy account of the latter's mental state). *The Uses of Psychiatry in the Law* is not so much a theoretical work as an overview of almost every topic conceivable. It discusses, quite well, the shifting development of the insanity defense, the concept of diminished responsibility, competency to stand trial, the psychopathic personality and the law (emphasizing the treatment difficulties that practically everyone experiences), and the relationship of drug addiction and violent crime. Perhaps because I have had some challenging cases in this area in my own private practice, I was especially intrigued by Dr. Bromberg's chapter on sexual crimes and sexual psychopathy. Often the general public is so revolted by such crimes and judges are under such public and political pressure to put those unfortunates who commit them "away" for long or indeterminate periods that it is no easy task for an examining psychiatrist to put into perspective—for judge and jury—the dynamics behind the offense.

The topics noted so far represent only part of the book's range. Dr. Bromberg looks at the role of mental illness in divorce and annulment. He touches on custody, including the famous *Painter v. Bannister* case in which prejudice against the father's "Bohemian" lifestyle played more of a role in the decision making than any psychological unfitness to be a good father on his part. Competency to enter into contracts, to make wills, and to testify as a witness is discussed (with an interesting analysis of Whittaker Chambers' testimony against Alger Hiss, especially the failure of the psychiatric expert witness for the defense to be adequately prepared). The increasingly strict safeguards that are required before an individual can be civilly committed are examined. Dr. Bromberg is candid about psychiatry's inability to predict "dangerousness" to self or others and how lawyers and the legal system hound psychiatrists into trying to make such predictions. The book considers psychiatrists' roles in testifying in personal injury and workman's compensation cases. It concludes with a discussion of the psychiatrist when he or she is involved in a lawsuit—for malpractice, failing to predict a suicide, or violating confidentiality. We learn that, after the California Supreme Court's ruling in the *Tarasoff* case, there is a duty to violate confidentiality to inform a potential victim that he or she may be at risk for harm by a particular patient. Indeed, one of the nice things about *The Uses of Psychiatry in the Law* is the descriptive table of important cases at the end of the volume.

The audience for this book is the general reader, lawyers, and psychiatrists. It is a survey, with a little bit on every topic, and would be a good addition to a medical library. Very few topics, however, are covered in much analytic depth—the book's size simply does not allow for it. But each chapter is a good starting point to get an overview of a particular area, and the footnotes and bibliography point the way to more detailed references.

Rather than having each chapter written by a different expert in the given field, as is *The Harvard Guide to Modern Psychiatry* (1), Dr. Bromberg has attempted the whole task of this book himself, drawing from his many years of practice as a forensic psychiatrist. One might expect that a synthesized, thematic view of the interaction of law and psychiatry might emerge, as it does in Dr. Alan Stone's *Mental Health and Law: A System in Transition* (2), but it does not. Dr. Bromberg chooses, instead, to bring us up to date on the current course of development over a wide range of topics in these two fields. He leaves the working out of the future path of development to us.

The Literary Freud: Mechanisms of Defense and the Poetic Will. Psychiatry and the Humanities, Vol. 4, *edited by Joseph H. Smith, M.D. New Haven, Conn., Yale University Press, 1980, 379 pp., $27.50.*

It is seldom noted and perhaps not widely known that Freud was awarded the Goethe Prize in 1930. This annual award was founded in 1927 by the City of Frankfurt for annual presentation to "a personality of established achievement whose creative work is worthy of an honour dedicated to Goethe's memory." It is also of interest that the first recipient of this honor was Stefan George (1868–1933), the German poet who led the revolt against realism in German literature through his aristocratic and esoteric lyric verse.

Freud was not well enough to travel to accept the prize ($2,500) and deliver the required address in person, so his daughter, Anna, read his "few sentences." In his brief remarks (1) he defended analysts against the reproach that "they forfeited the right to place themselves under the patronage of Goethe because we have offended against the respect due to him by trying to apply analysis to him himself. I would dispute at once any degradation is intended or implied by this" (1, p. 211).

In the volume of 12 evocative essays under review, there is no parallel apology for the attempt on the part of literary criticism to illuminate or clarify the Freudian text, presumably not open to clarification or amplification by psychoanalytic clinical methodology per se. What therefore emerges is a fascinating literary exegesis of some Freudian metapsychological texts, "in the absence of clinical evidence."

This collection of essays is in line with a whole new concept of applied psychoanalysis, in which Freudian theory is more likely to be employed by nonanalysts in elucidation of their own discipline. These applications in effect basically modify Freudian concepts themselves. These highly provocative essays are introduced by the title paper of the volume, "Freud's Concept of Defense and the Poetic Will" by the eminent literary critic Harold Bloom. His discussion opens with the immediate equation of defense and troping, or the use of figures of speech. (This sets the style of the paper, which is saturated with figures of speech and undoubtedly will send many readers to their dictionaries.) Bloom leads us through a discussion of Shelley's defense of poetry against Thomas Love Peacock's characterization of it as "rubbish of departed ignorance" to an elaborate chapter-by-chapter analysis of Freud's "Beyond the Pleasure Principle" (2), which he seeks to interpret as "a dialectical lyric—indeed, as a post-Romantic crisis lyric" (p. 11). It may be gratuitous to remind the reader that in "Beyond the Pleasure Principle" Freud introduced his most controversial and least accepted metapsychological concept, that of a death instinct, "the urge inherent in organic life to restore an earlier state of things" (2, p. 36).

For example, chapter one of "Beyond the Pleasure Principle" is an allegory or irony in that it says the pleasure principle has priority over the constancy principle only to relieve the analyst of allegiance to nineteenth-century biology and physics. Bloom terms chapter two a "tessera" (a token or password), "an antithetical completion that fails to complete." In this chapter Freud "tacitly and perhaps unknowingly . . . lets us understand that his own earlier synechdoches were incomplete" (p. 14). The synechdoche Bloom refers to at this point is what he referred to earlier as "Freud's highly characteristic synechdoche of neurosis as mutilated part and psychic health as macrocosmic unity" (p. 14). Chapters one and two are discontinuous; the latter is disjunctive in itself because it considers traumatic neurosis and children's play, which are antithetical. Chapter three is labeled Freud's "kenosis" or "emptying himself," as Christ did on becoming a man. Bloom suggests that "we can observe Freud defending his psychoanalytic strength by isolating too rigorously a crucial element in his praxis: the transference."

Chapter four is an "indeliberate exercise in the grotesque, with much of its rhetoric a curious litotes [understatement], and with its argument colored by images of depth"(p. 16). This chapter also reveals Freud's defense against biologism, "a repressed movement from scientism to speculation" (p. 16).

Chapter five is an "askess" or sublimation of the problematic theory of drives with Freud's new metaphor that drives are but "circuitous paths to death." Chapter six is "that final movement I have named by the ratio of apophades, which in rhetoric is the modes of transumption and in poetry is manifested through images of earliness and lateness" (p. 18). Chapter seven is an extension that reveals "the hidden Freudian metalepsis," for example, the literal meaning being death while the figurative one is Eros. Bloom at this point terms the death instinct formulation "outrageously speculative" although of unsettling originality, and he concludes that the drives and defenses are modeled on poetic rhetoric whether or not one believes with Lacan that the unconscious is structured like a language. At one point in this literary and highly "speculative" exposition, Bloom lets the cat out of the bag, to use a trope. He writes, "Granting that I merely seem to be playing with figurations, permit me to extend the play for a space" (p. 21). These examples from the paper have been multiplied to give an adequate sense of its flavor, so to speak. Indeed, one cannot deny the intricacy, the wealth of allusions, the literary cleverness of the essay, but one can muse or be bemused over its clinical or scientific relevance. Of course, this in no way reflects on its merit as literary critique of a famous psychoanalytic text as literature.

The 11 other eminent contributors from major universities and psychiatric centers of learning range over a wide area of related topics from Blake and Freud to Freud and Hart to "The Articulation of the Ego in the English Renaissance." Many reveal the current great interest in the revisionist French psychoanalyst Jacques Lacan. S.H. Brisman and L. Brisman, in their essay "Lies Against Solitude: Symbolic, Imaginary and Real," advance a revisionary idea of their own, namely, that Lacan's notion of the unconscious is structured like a language be restated that the unconscious is structured by language.

Marshall Edelston, in "Two Questions About Psychoanalysis and Poetry," suggests that analysts should read poetry because the same mind that produces dreams, parapraxes, and symptoms also writes poetry. Thus psychoanalysis must propound a theory of mind that also explains its poetic proclivities.

There is no end to the interesting points these 12 essays offer the interested reader, replete as they are with literary, psychological, and psychoanalytic allusions and insights. I can only strongly recommend it as a literary and intellectual feast indeed. To do justice to all of the essays would require a lengthy review of each.

Individual and Family Therapy: Toward an Integration, *by Fred M. Sander, M.D. New York, N.Y., Jason Aronson, 1979, 235 pp., $20.00.*

In *The Structure of Scientific Revolutions* Kuhn (1) remarked that a new method of observation can initiate a paradigm shift without a crisis having developed in "normal science." Naturalistic observation of patients in their families is a very different vantage point from that of the psychoanalytic situation. The new data it produced led to new concepts, new theories, and new approaches to therapy. Early observers of families adopted contemporary models from neighboring hard sciences, as Freud had done in his era. The models had changed to those of ecology, information exchange, and contextual interactions: the systems paradigm. Family therapists are developing new concepts to convey the newly described phenomena they are working with.

Fred Sander's book is an excellent introduction to the process of integrating the family perspective into general psychiatry for those therapists trained in traditional psychoanalytically oriented psychotherapy. Dr. Sander's talents as a teacher and scholar illuminate the essential assumptions of psychoanalysis and family therapy, which he illustrates with discussions of several dramatic plays. He uses excerpts from *Hamlet* to characterize the psychoanalytic approach and to begin reflection on the paradigm shift involved in thinking about life from a family systems perspective:

> There is general agreement that Hamlet's internal oedipal conflict was complicated by a family situation that *in reality* directly mirrored his unconscious fantasies. Although, as we mentioned earlier, his conflicts were fairly well internalized, he was also embroiled in a rather severe ongoing pathological family system marked by denial, externalization, projection, and acting out. (p. 15)

Dr. Sander remarks that psychoanalysis has "chosen not to deal directly with such external realities except to acknowledge that psychoanalytic treatment is usually not indicated at such times" (p. 16).

In a fascinating chapter organized around Eliot's *The Cocktail Party* (in which he uses action from the play to illustrate various family therapy ideas) Dr. Sander traces the emergence of the major trends in family therapy during the 1950s and 1960s. Albee's *Who's Afraid of Virginia Woolf* and Eliot's *The Family Reunion* serve to bind together some ideas about "Childlessness and the Family Life Cycle (chapter three) and "Schizophrenia and the Family" (chapter four).

Dr. Sander is a classically trained psychoanalyst who also has long experience in family therapy, and he is eminently qualified to survey both areas. He spends 70 pages in a scholarly exegesis of Freud's position on marriage and the family and of recent psychoanalytic views, noting the lack of any systematic study of the problems of marriage or the interplay of the marital relationship with child development in the vast psychoanalytic literature. He then gives a too brief description of the scope of the eclectic family therapy literature course he and Chris Beals originally taught at the Albert Einstein College of Medicine. The clinical practices of the leading family therapists are touched on. In a set of clinical examples, Dr. Sander gives his views on the usefulness of both the individual and the family paradigms. His concluding chapter uses both to analyze Wilde's *Salome*.

The underlying premise of the book is

> that the polarization of individual/intrapsychic and family/interpersonal approaches is an artificial one. We need to understand in what ways the individual approach affects individuals and family systems as we need to know how the family systems approaches affect change in families and individuals. (p. 181)

Dr. Sander's style is clear and readable, and his bibliography is an excellent guide to the literature. His book is a valuable introductory text.

Psychiatric Factors in Drug Abuse, *edited by Roy W. Pickens, Ph.D., and Leonard L. Heston, M.D. New York, N.Y., Grune & Stratton, 1979, 372 pp., $19.50.*

One impressive feature of this book is the rapidity of its publication. It represents the proceedings of a conference held at the University of Minnesota in March 1979. Grune & Stratton, through a process called Rapid Manuscript Reproduction, have brought us a book more up-to-date than most.

There was a pleasant irony in the fact that I was asked to review this book. The conference, like many of the best continuing medical education (CME) courses at the annual meeting of the American Psychiatric Association, attracted many people and was filled early. My application arrived late and was turned down.

Thirty-five authors have contributed 17 review papers ranging from basic psychopathology to more esoteric subjects, such as alcoholism in anorexia nervosa. Each chapter has a good bibliography, the longest of which is Ellinwood's, with 122 citations on drug-induced psychosis. A computer search of the world literature on this subject alone would have cost more than the entire book, would have been much less selective, and probably would have been less complete.

Although the book has a special interest for researchers and teachers, there is much that is relevant to the practicing clinician. Jaffe and Kanzler's chapter on "Smoking as a Psychiatric Disorder" provides a reasoned perspective to the acrimonious debate that took place when tobacco use disorders were first proposed for inclusion in *DSM-III*. They begin with Sir Humphrey Ralston's 1926 statement that "to regard tobacco as a drug of addiction may be all very well in

a humorous sense, but it is hardly accurate." Their review of the psychological, pharmacological, biological, and treatment data provides a beautiful conceptual overview of the main issues in drug abuse.

The opening chapter by Schuster, Renault, and Blaine on the "Relationship of Psychopathology to Non-Medical Drug Use" is a classic. It should be read by every physician whose medical education created the impression that alcoholism or drug dependence always represents severe psychopathology. The authors present a balanced, well-documented review of both the animal and human literature to point out the continuum of nonmedical drug use that exists from normality through psychosis. They conclude that "drug taking is biologically normal and society must learn to live with that fact and to develop the necessary constraints to prevent unregulated drug use." Their material has provided a new introduction to my substance abuse course for second-year medical students.

Of similar basic medical educational value is Schaefer's article on "Ethnic Differences in Response to Alcohol." His review of the biocultural data effectively illustrates the complexity of the nature-nurture argument. In spite of the fact that "seven of twelve comparisons indicate American Indians have *faster* rates of ethanol disappearance," the "firewater myth" continues to be used as a form of ethnic one-upmanship to prove that Indians cannot hold their liquor.

There is a wealth of other useful information in this book, which illustrates both the depth and respectability of psychiatric interest in drug abuse. There is little direct information on treatment, but the material provided will add knowledge and perspective to the efforts of those of us who treat alcohol and drug abuse.

JOHN N. CHAPPEL, M.D.
Reno, Nev.

Delirium: Acute Brain Failure in Man, *by Z.J. Lipowski, M.D. Springfield, Ill., Charles C Thomas, 1980, 548 pp., $39.75.*

Surprisingly, as the author points out, before this work no book about delirium has been published in English. "Delirium" derives from the Latin word for "furrow," making the literal meaning close to the modern idiom "off the track." The author defines delirium as a "psychiatric syndrome characterized by a transient disorganization of a wide range of cognitive functions due to widespread derangement of cerebral metabolism."

The volume consists of two main sections. The first deals with clinical features and psychopathology of delirium and is followed by a chapter on etiology. This chapter provides the framework for the second part of the volume. A separate chapter addresses pathophysiology and provides an extensive and current review of cerebral blood flow, electroencephalography, and contemporary physiologic concepts of arousal and hypnogenic systems. The remaining chapters in this section deal with the diagnosis and management of delirium. The second part of the volume deals with the various organic causes of delirium and provides an extraordinarily complete review of the wide range of diseases producing delirium.

This is an excellent book that deserves a large audience. Residents and house officers will benefit from its systematic approach to diagnosis and differential diagnosis. Family practitioners, internists, and surgeons will find the second section of the book useful because of its encyclopedic review of the causes of delirium.

Neurologists and organically oriented psychiatrists will find much to learn in the review of pathophysiology and pathogenesis. The bibliography is extensive and current, with citations as recent as 1978. The merits of this book should give it a long half-life and justify the enormous effort that Dr. Lipowski has put into it.

DAVID D. DALY, M.D.
Dallas, Tex.

Exhibitionism: Description, Assessment, and Treatment, *edited by Daniel J. Cox and Reid J. Daitzman. New York, N.Y., Garland STPM Press, 1980, 392 pp., $27.50.*

The title of this volume is somewhat misleading. It does deal solely with exhibitionism, but it would more aptly be titled *The Behavioral Assessment and Treatment of Exhibitionism*. Although there is one chapter each on psychodynamic group therapy, psychoanalytic theory and treatment, and the integration of behavioral and psychodynamic approaches, the remaining 10 chapters are entirely from a behavioral perspective, with two on forensic considerations.

The foregoing is not meant to detract from the book's value. It contains some of the best written, fully described, well-documented, and carefully followed up expositions of behavior therapy for exhibitionists I have seen. With respect to assessment, several of the chapters, especially those by Brownell and by Murphy and associates, are explicit and informative about the various aspects of exhibitionism that must be separately assessed, and how these distinguishable facets variably affect treatment.

Various individual and combined forms of behavior modification therapy, along with available follow-up data, are described in separate chapters. Although there is some inevitable unevenness, in general they meet the essential test of leaving even the nonbehaviorist reader with the confident sense of having understood the procedure and the rationale. An outstanding chapter is Maletsky's lengthy, elegantly written summary of about a decade of clinical research and therapy, including detailed descriptions of techniques, with 186 exhibitionists. Even more impressive is the careful follow-up indicating a failure rate of only 12.4%.

The two chapters on legal considerations are concise, practical, and reasonably comprehensive. The chapter by Rhoads on psychodynamic and behavioral integration is admirably well balanced but, unfortunately, far too simplified. He offers some useful suggestions and illustrations of a combined approach. Mathis' chapter on group therapy is solid and practical. Allen's psychoanalytic chapter is a sound review of psychoanalytic theory and the psychodynamics of exhibitionism, but it is badly obscured by the jargon of psychoanalytic metatheory, which invariably compromises both comprehension and credibility.

There are three matters with which I take issue. First, the chapter on exhibitionists' victims seems carelessly reasoned. Exhibitionism is a common behavior, and the very small percentage of women who report being significantly disturbed by the experience translates into a sizable number. The fact that some women are psychologically vulnerable to

this experience is conceptually very different from regarding the act as intrinsically damaging. This is not to dismiss the offensiveness of exhibitionism but to emphasize that the real victim of this perversion is almost always the exhibitionist.

Second, the point is repeatedly made that exhibitionists seldom escalate to more serious or violent sexual offenses. True, but the fact that many violent sexual criminals report exhibitionism before becoming sexually violent is ignored. These are not statistically inconsistent facts, nor is the matter academic. It is crucial to explore carefully and explicitly for violent sexual fantasies, dreams, or thoughts when one is evaluating an exhibitionist, to help differentiate those few who may need far more careful management and surveillance and whose treatment plans may need to be especially tailored to prevent violence.

Finally, the description of exhibitionists is thin to the point of uselessness in understanding these people when it fails to include a description of what is going on intrapsychically, dynamically, and developmentally.

The data presented are convincing that behavioral therapy is the treatment of choice, by any criterion, for symptomatic relief in the great majority of exhibitionists. Within its scope, this is a good book, to be confidently recommended. One might wish only that its scope were broader. The ultimate relief of a pathological condition is its prevention, which requires exquisite understanding of its etiology and development. Behaviorism cannot suffice in this task regarding exhibitionism as well as it can in devising effective therapy.

WARREN J. GADPAILLE, M.D.
Englewood, Colo.

Health and the Family, *edited by Clive Wood. London, England, Academic Press, 1979, 235 pp., $27.00.*

This slim volume reports the proceedings of a conference sponsored jointly by the Royal Society of Medicine and the Royal Society of Medicine Foundation held at the University of Cincinnati Medical Center in 1978. The contributors include eight distinguished scientists and educators from the United Kingdom as well as 19 notable scientists, educators, and administrators from the United States. There is a broad spectrum of presentations dealing comprehensively with the changing role of the family in contemporary life, some of the dramatic advances in medicine in modern times, and the interface of the two phenomena. Is the family disintegrating in a setting of greater social, sexual, and economic freedom for women, along with a mounting divorce rate? Are new or other forms of human relationships superseding the role of the family? Are the health professions providing adequate services to individuals and families? Can the health professions enunciate more clearly the role of intrafamilial stress in social and physiological disequilibrium, and can they intervene in a preventive or therapeutic fashion? What are the strengths and weaknesses of current training programs for physicians?

These are some of the issues to which the contributors address themselves. A well-known sociologist once noted that he was much more interested in raising the right questions than in trying to formulate the correct answers. The present volume provides even-handed responses from both sides of the Atlantic, but in the sense of searching for solutions rather than providing final answers.

Many of the presentations are most relevant to health educators, primary care physicians, and public health specialists. Also, there is important information for health care students in terms of "the shape of things to come."

In view of the continuing neglect of the behavioral sciences in medical school and residency training, psychiatrists may be increasingly called on to round out the trainees' views of individuals and families. From that perspective, they would derive significant benefit from the whole book, which cannot be reviewed in detail here.

I have chosen to focus on a few areas of unusual stress that are common in many families and may be of particular interest to psychiatrists. Christopher F. Clulow of the Institute of Marital Studies, Tavistock Institute of Human Relations, London, and his colleagues have been engaged in a study of the first baby and stress. The changes attendant on the coming of the first child can so disrupt a couple's patterns of living as to be a major life crisis. During pregnancy and following birth, the father may feel neglected and seek solace with another woman, the mother may become depressed, marital satisfactions may diminish, and there may be deterioration of family income and housing accommodations. Either spouse may develop somatic symptoms, and sexual problems often occur. Antenatal and subsequent classes for parents usually focus on the physical and superficial social aspects of the situation. The wife may feel the sole responsibility for the husband's perception that he is being neglected. Actually, little attention is given to the effect of the advent of the baby on the marriage until one spouse or the couple reach the breaking point.

Dr. Clulow and his associates initiated a two-pronged project to study and possibly rectify some of these deficiencies. Small groups of couples were seen by two project workers and a visiting nurse for a period beginning late in the pregnancy and continuing for six sessions, terminating about 6 months after the baby was born. Attention was directed to the couple's talking about their preoccupations, their becoming aware of feelings about the changes required by pregnancy and birth, and discussion of means of coping with these. The rationale for this approach was that by making time available for such reflection, the couples would be better prepared to face anxiety and contain stress.

In addition, project members initiated workshops for visiting nurses to help them perceive and evaluate the effect of the first baby on the marriage relationship and to delineate the role of the visiting nurse. This 18-month project had not been entirely completed at the time of the presentation, but on the surface it seems to have a great deal of merit.

Family-centered birth is presented in considerable detail by Edward J. Quilligan, Professor of Obstetrics and Gynecology, University of Southern California, Los Angeles. Of interest to psychiatrists is the finding that family-centered birth in a hospital setting can improve the relationship between the spouses and increase the process of bonding between mother and infant and father and infant.

Donald G. Langsley, Professor of Psychiatry, University of Cincinnati, reviews the literature on the physician and family crises. Death of a spouse has been rated as the most severe stress, followed by divorce and then by marital separation. According to current trends, 35%–40% of all marriages end in divorce, and this does not include those who have formal or informal separation. Of people seeking psychotherapy, 50% complain of marital difficulties and another 25% report problems related to marriage. Despite these find-

ings and despite the fact that 60% of patients with emotional problems are cared for by primary physicians, the latter often deny that marriage problems are in their area of responsibility.

Langsley reviews several classifications of marriages from a dynamic as well as from a developmental point of view. The axes in these configurations include power, intimacy, and boundaries. He refers to the work of Cuber and Harroff (1), which focused on intimacy. In the conflict-habituated marriage, there is constant tension and the marriage persists only through fear of loneliness. In the devitalized marriage, overt problems are barely evident and numbness and apathy hold sway. In the passive congenial marriage, there is some sharing of interests, but a lack of intense emotional involvement. The vital marriage is described as exciting and rewarding and marked by enthusiasm. Finally, the total marriage has even greater intensity and involvement and each partner sees the other as indispensable.

Langsley goes on to invite the primary physician to use some of the classifications to define the problems in a given troubled marriage, including communication problems and role performance. Then he speaks of developing a therapeutic alliance in brief-treatment marriage therapy. He encourages the primary physician to engage in this kind of treatment rather than referring couples to specialists. This can facilitate continuity of care and promote the diminution of stress and chronic crisis. I am confident that some physicians may be able to function well in this role. However, I wonder whether ongoing workshops as described by Clulow for visiting nurses might be relevant with primary physicians. In addition, psychiatrists to whom couples are referred for treatment might profit by Langsley's suggestions and by greater familiarity with the studies he mentions.

Object Relations and the Developing Ego in Therapy, *by Althea J. Horner. New York, N.Y., Jason Aronson, 1979, 341 pp., $20.00.*

The increasing psychoanalytic interest in preoedipal psychopathology and the development of object relations theory has led to a burgeoning literature that attempts to relate early childhood development to adult phenomena. In her careful descriptions of the subphases of the separation-individuation process, Margaret Mahler has offered clinicians a way to help their patients put into words their often inchoate anxiety, which interferes with the development of trusting interchanges in the therapeutic process. In this book Dr. Althea Horner attempts to bring together Mahler's ideas, object relations theory, and attachment theory with elements of self-psychology and Piagetian thinking in a formulation of the origins of preoedipal difficulties and their reflections in the intensive psychotherapy of adults. This integrative task is a difficult one; with some reservations, I think she succeeds rather well.

Dr. Horner reviews the early formation of attachment bonds between mother and infant and the process of gradual separation and formation of a cohesive self, suggesting very specific correlates of these stages in the clinical material of her adult patients. Although her certainty about her correlations is somewhat troublesome, she does take clear positions, and her clinical material is rich, varied, and well selected to illustrate the sources of her formulations in the transference observations. She makes complex and clinically useful distinctions between the pathology of schizoid, psychopathic, masochistic, false-self, borderline, narcissistic, and "preneurotic" personality disorders.

There is considerable controversy in the literature about the origin of narcissistic and borderline phenomena in infancy. Using Kohut's formulations of the origins of narcissistic transferences in the childhood phases of the grandiose self and the idealized object, Horner relates these structures to specific subphases: the grandiose self to the elation of the "practicing" period and the idealized object to the panic and dependency of the "rapprochement crisis." Her complex descriptions of the interpersonal, intrapsychic, and affective details of these stages and of the patients' defensive use of the related intrapsychic structures provide useful guidelines for therapeutic intervention.

Horner suggests that both borderline and narcissistic patients experience major trauma during the rapprochement crisis and that borderline patients retreat to their preexisitng self-fragmentation, derived from the symbiotic phase, while narcissistic patients, with more cohesive selves, can use the grandiose self of the practicing phase. She differentiates certain patients' use of grandiosity as a regressive defense against the shame of oedipal failure (in the preneurotic patient) from the more primitive narcissistic patients' use of grandiosity to defend against the anxiety and shame of dependency when there is a less differentiated self and the absence of object constancy.

The book requires work and sophistication on the part of the reader. The rather spare index is not helpful to the reader who might be confused by the welter of concepts. Metapsychological concepts are freely used and tend to be reified. One statement, for instance, reads,

> A significant aspect of being the designated good object is to function as proxy for the rage that the good self must not experience lest it become the bad self and therefore subject to the hate directed at the bad object with whom it is still symbiotically bound and identified.

Despite my own familiarity with these concepts, my mind begins to fade and lose touch with the clinical experience when faced with such abstruse language. Too often, I think, the patient's experience appears to be colored by these theoretical constructs (e.g., one patient reports, "I never had the correct merger experience as a child"), and it is not always clear whether the patient's experience is being correctly understood or whether a new language is being taught. Dr. Horner is, however, quite sensitive to the dangers of the therapist's "knowing too much" and impinging on the patient's privacy and autonomy. Her descriptions of the therapeutic task with these patients and of the patient's need to use the therapist as "mediator of organization" are clear and concise.

Despite the drawbacks of the book, Dr. Horner presents rich and useful ideas for formulating and working dynamically with severely limited patients. Her integrative formulation

of preoedipal pathology is both useful and practical, and I can recommend the book (with the above reservations) for the practicing clinician.

EDWARD R. SHAPIRO, M.D.
Belmont, Mass.

And They Took Themselves Wives: The Emergence of Patriarchy in Western Civilization, *by David Bakan. San Francisco, Calif., Harper & Row, 1979, 179 pp., $10.00.*

In this book David Bakan has produced a succinct, scholarly, and rather timely work. Based on the author's 1976 Terry lectures at Yale University, the book is both an explication of the historical development of Judeo-Christian patriarchy and a defense of the familial values established by that tradition. Leaving room for some disagreement, Dr. Bakan, a professor of psychology and a Talmudic scholar, maintains that the Bible is associated with "what is perhaps the most important step toward the reduction of male-female sex-role differences in the history of civilization." The step alluded to refers to a transition from an ancient Semitic matriarchal society, characterized by the absence of a patrilineal incest taboo and organized geographically by matrilineal clan, to the relatively recent patriarchal structure. Why did this change occur? According to Bakan the ideology of patrilineality was necessary for both the stability of family life, since it established male responsibility for children, and for the survival of the greater society, since it allowed unification of geographically dispersed tribes. Christianity is seen as the natural sociologic outgrowth of patrilineality, since it extends unification still further in allowing brotherhood to exist through faith. The book's scholarship contributes in part to one of its faults. Requiring extensive reference to primary Biblical sources and frequent use of a consonantal text, the book becomes difficult to read. Still there are diversions. Vance Packard is quoted in an analysis of cake symbolism and Kate Millett is in the index along with Ovid, Abraham, and Punch and Judy.

Elaine Pagels' recent book *The Gnostic Gospels* (1) suggests that one of the most striking differences between the orthodox sources used by Bakan and the heretical ones is that the latter often described God in both feminine and masculine but still specifically Christian terms. One wonders what Dr. Bakan would make of this, since the unorthodox texts would support the existence of a viable extended kinship structure organized along more than simply patrilineal lines. This points to an additional concern for the reader. As noted in the previous quotation and as is summarized in the book's conclusion, the author uses Judeo-Christian history to discuss the nature of the male-female role differences, the future of the family, and "the welfare of the total society" of man. It is difficult to rationalize engaging in these broader statements without reference to the contributions of non-Western civilizations. Similarly, a study of family structure in primitive societies creates some doubt as to the logic or universality of the progression that the author outlines. Ernest Crawley, in his classic work *The Mystic Rose* (2), pointed out that even in the most primitive tribes studied, paternal descent is nearly as common as maternal. These are small points, however, and should not distract the reader from the real worth of this book. It is thoughtful, has a sense of history, and should interest a broad audience of readers.

San Francisco, Calif.

Psychedelic Drugs Reconsidered, *by Lester Grinspoon and James B. Bakalar. New York, N.Y., Basic Books, 1979, 334 pp., $15.95.*

This book is the third of what appear to be the authors' attempts to provide the nonspecialist with information necessary to informed public policy concerning "drugs of abuse." (Previous volumes dealt with marijuana and cocaine.) After a first semitechnical chapter concerning sources, botanical and otherwise, chemical structure, dose, mode of action, and effects, Grinspoon and Bakalar go on to describe psychedelic use in pre-industrial society and its more recent history from Priestley (nitrous oxide) through Weir Mitchell, William James, Klüver, Hofman, Leary, and finally to legal controls and seeming disinterest. Other chapters present the phenomenology of the response to psychedelic drugs in exquisite detail, the infrequent adverse reactions, and the drugs' questionable therapeutic effects. Final chapters deal with implications of the drug-induced response and a plea for continued or, more accurately, renewed research. An appendix describes the current legal situation regarding psychedelic drug use; the book ends with an excellent, interesting, but not exhaustive bibliography and an index.

Although as a former active participant in some of the controversies concerning their free use in the community I may not bring objectivity, I certainly bring interest and, presumably, knowledge. The facts seem accurate, the semifacts accurately stated. Curiously, even for an interested reader, as William James (and the authors) pointed out, the phenomenology of "phantasms" is "intolerably dull." It is not easy to pay close and critical attention to somebody else's ineffable or ecstatic experience. To my mind, the authors (despite their own caveats) take too literally the reports of birth experiences as possibly reflective of real, specific memory traces rather than personal or cultural retrospective interpretation of something of the commonality of being human. They potentially mistake metaphoric for material connections. The surface similarity of some psychedelically induced mystical experiences and the Heisenberg uncertainty principle does not suggest a possible underlying world order; while analogous, they are unlikely to be homologous.

Our science does, however, need to pay attention to these phenomena. The ineffable needs to be accounted for rather than dismissed. William James said, "No account of the universe in its totality can be final which leaves these other forms of consciousness quite disregarded. . . They forbid a premature closing of our accounts with reality" (1, p. 388). Now that the flower children have faded and the political uproar is past its peak, Grinspoon and Bakalar do us a service by redirecting our attention to important unresolved issues: what do these drugs do, how do they do it, and how may their effects be used as a tool of science, as treatment, and as a mechanism to help us enlarge our view of our humanity?

New York, N.Y.

Sexual Excitement: Dynamics of Erotic Life, *by Robert J. Stoller, M.D. New York, N.Y., Pantheon Books, 1979, 271 pp., $11.95.*

In this, his fifth book on sexuality, Dr. Stoller serves the reader a rich and highly seasoned feast for the mind. Like most psychoanalytic writing, the book fits into no neat category but falls somewhere between the technical and the popular, the scientific and the poetic. Unlike much analytic writing, however, it is free of the turgidity, circumlocution, and jargon that afflict so many contributions to that troubled field. Even when he is discursive and tangential, and in this book he sometimes is, Dr. Stoller maintains a vigorous style that carries the reader with him. In fact, the self-confident, direct, even exuberant tone of the book, which gives it its engaging quality, sometimes loosens its argument.

What we have here are two or three books in one: 1) an erudite discourse on sexual arousal and gender identity, reflecting Dr. Stoller's own clear expertise in these matters, 2) an analytic case study of a high-functioning hysterical patient called Belle and of her sadomasochistic fantasy, and 3) an essay on mind, self, consciousness, will, and morality.

This is a book that is chock-full of ideas. Even when the writing wanders far afield, it remains rich in content and stimulating in style. One finds insights, observations, and vignettes strewn like nuggets throughout the text, the footnotes, and the appendixes.

Dr. Stoller's central thesis is that fantasy is an essential component of most people's erotic life and that hostility is a ubiquitous element in most people's erotic fantasy. The hostility is not inborn, nor is it inevitable. It is a device to undo childhood humiliation and to turn defeat into triumph. It is so common because childhood trauma is so common. The essence of therapeutic healing is achievement of such self-understanding and acceptance that one can give up the need for revenge and remove the element of hostility from one's cherished relationships. Rather than a defense of or an apologia for hostility in sexual activity, the book is an elaborate explanation of it and describes at least one method, psychoanalysis, to overcome it. Stoller is *not* a Sade in analytic clothing.

Belle, the subject of the book, is vividly portrayed as a woman of much grace, beauty, and wit. Obviously, Stoller likes her—and so will the reader. The evolution of her personality and her sexual life and the course of her therapy are well documented and flow with forceful logic. Through detailed illustration and description one comes to see her as the paradigm of all neurotic patients, maybe of all people, and as a three-layered creature: an outward shell of rationality that conceals a middle layer of irrational, primitive, and vindictive fantasy, which in turn encloses an inner core of sanity and integrity. The emergence of that inner core into the full light of day is the aim of successful therapy and of successful personal development.

As mentioned above, this is really more than one book. The reader with limited time and endurance is advised to skip part three, Theories of the Mind, and proceed from part two, Data: Belle, to part four, Conclusion. In doing so, he or she would get the full account of Belle's analysis and a great deal more about sexuality and therapy (the discussion of sadomasochism is particularly outstanding and illuminating). What he or she will miss is a lively, even bold discussion of certain profound psychological-philosophic-existential issues. The author does not shrink from tackling head-on such knotty matters as the meaning of "I," the reality of the self, the mind-brain dichotomy, the role of conflict in personality development, the primacy of aggression, and the question of free will. In doing so, he takes the unusual step of inviting commentaries on these matters from two people who have given much thought to them: M.F. Basch and K.M. Colby. Their contributions appear as Appendix A—a gem of lucid discourse on extremely complex subjects. In fact, part three of the text and this appendix, along with references and annotations pertaining to them, can be viewed as a separate and worthy document in themselves.

Some of the style and content of the book can best be conveyed through quotations:

> Psychoanalysis is the subjective study of subjectivity struggling to become the objective study of subjectivity. (p. 193)

> Analysis, with astonishing speed, went from revolution to respectability to outdated mythology. I do not think that a free society can easily bear the loss. (p. 223)

> Considering how appalling existence is for most humans, we in our society are lucky to be able to wring our hands over flawed sexual pleasure. (p. 4)

> My theory makes sexual excitement just one more example of what others have said for millennia: that humans are not a very loving species—especially when they make love. Too bad. (p. 35)

> Although it is old-fashioned to say that they exist, it is no secret that there are women with richly textured and complex femininity who meet anyone's criteria for psychic health. Their femininity is a product of a solid core of gender identity, permanent and non-conflict-laden identifications with feminine women, and successful grappling with and mastery of oedipal conflicts in which they participated with their mothers and fathers. We need not doubt it; they unthinkingly, comfortably accept having female bodies that are sources of physical pleasure. Should they marry and have children, they draw from their femininity a capacity for mothering in which there is so little hostility that, with the help of their masculine husbands, they raise their sons to be masculine and their daughters feminine. (pp. 55–56)

> Let us call her Belle, for that suggests how she felt she was when analysis began: old-fashioned femininity; a touch of exhibitionism; gentle masochism; a slightly addled yet refreshing innocence; soft, round, dreamy erotism; an unbounded focus on males, romance, silken garments, flowers and beads, bosoms, bare behinds and babies. (p. 59)

> More and more I think success in analysis depends on the patient's need to be honest. (p. 65)

> Sadomasochism is, I think, a central feature of most sexual excitement. My hunch is that the desire to hurt

others in retaliation for having been hurt is essential for most people's sexual excitement all the time but not for all people's excitement all the time. (p. 113)

Perhaps the perversion of masochism is a hungry search for skin and mucuous-membrane stimulation in people who got too little in infancy and who have decided, as have "moral masochists," that any attention, even if painful, is better than none. . . . Bak makes the suggestion that sadomasochistic fantasies, especially those of being immobilized, represent the wish not to be separated from mother. . . . I find the involved and unconscious dynamics of sadomasochism more clever, more intelligent, and more sly than is suggested by the sacrificial ego model: we inflict punishment on ourselves in order to avoid having to change. . . . Guilt is not the price paid for being bad but the price paid for the privilege of continuing to be bad. The megalomania of guilt: I fool everyone. . . . I do not think people become masochistic because they truly believe they deserve to be punished. Rather, I think they trick themselves and us into believing that that is what they do, while secretly, they are busy with their foxy little sadisms. (pp. 118–124)

With what, would Colby ask, does consciousness provide us that could not be accomplished without consciousness? My answer is the same, I think, as Freud's. The value of consciousness is pleasure and pain, an effective motivating system: the present models for behavior, such as computers and their programs, will be closer approximations when they can itch as well as scratch. (p. 181)

We still go on living convinced at bottom that we make our own choices. No one, not even a madman, knows he is just a machine. No scientist really believes in the determinism he reveals in his laboratory. . . . In these gentle and liberal times, it is the style in some circles to call off the moralists and to see us all as victims free from the accusation of sin because our behavior is determined: choice is an illusion. But take the battering father. We know it was predetermined he would batter his child, in part, because he too was battered when little. Yet even at the hottest point of his rage, when he lifts his arm to bash in his baby's skull, there is a moment when, were he not indulging himself, he would hold back his hand. Most parents take advantage of their children because the poor things are little. . . . In other words, though it may nowadays be in bad taste, it may nonetheless be scientifically accurate to go back to—even assign responsibility to—parents for what they do to their children. (pp. 200–201)

When one considers how often the subject of sexuality is given such dull treatment in the literature, it is both fortunate and appropriate to find an exciting book on sexual excitement. That it is two books in one need not detract from its value to the reader who is duly warned; in fact, he or she can look upon it as a bonus and a bargain in these inflated times. Good printing, an eye-catching dust jacket, references, generous annotations, and an index round out a happy publishing event.

JOHN RACY, M.D.
Tucson, Ariz.

Electroshock: Its Brain-Disabling Effects, *by Peter Roger Breggin. New York, Springer Publishing Co., 1979, 237 pp., $17.95.*

In this book Dr. Breggin sets out to prove that ECT is not therapeutically effective and that, instead, it produces severe brain damage and irreversible mental dysfunction in most, if not all, of those who have received it. He bases his "proof" on what the dust jacket correctly describes as an "original" analysis of the ECT literature along with some anecdotal reports of dissatisfied patients. After admitting that his conclusions are not shared by most others in the psychiatric community (1), Dr. Breggin attempts to explain this discrepancy in terms of some sort of vague conspiracy on the part of "ECT advocates," who he insinuates have misled both patients and colleagues for some presumably nefarious purpose that is left unclear to the reader. Unfortunately, a true resolution of these differences is beyond the scope of Dr. Breggin's book, since, both quantitatively and qualitatively, factual inaccuracies and notable absences ensure an exceedingly biased presentation.

In actuality, the issue of persistent CNS side effects with ECT, currently under active investigation in this country and abroad, is certainly not as simplistic as Dr. Breggin would have it. Although there is some evidence that persistent subtle deficits, chiefly in the area of personal memory, may in fact occasionally occur in individuals following ECT, the vast bulk of both clinical and experimental evidence suggests that the picture of profound, irreversible impairment presented by Dr. Breggin is clearly not a common occurrence. For a more accurate view of what ECT does and does not do, the interested reader is referred to the report on ECT by the American Psychiatric Association (1), the proceedings of an NIMH-sponsored multidisciplinary conference (2), and the encyclopedic text by Fink (3).

Understanding and Helping the Schizophrenic: A Guide for Family and Friends, *by Silvano Arieti, M.D. New York, N.Y., Basic Books, 1979, 228 pp., $10.95.*

This clearly written and sensible short book from the pen of an eminent writer, clinician, and teacher is admirably suited to its purpose. The families and friends of schizophrenic patients will find here the facts, perspective, and tempered optimism they need while striving for balance in the face of psychosis. Some patients will profit from reading it also.

Too often treatment plans for schizophrenic illnesses minimize the importance of family support and education. Dr. Arieti has produced a therapeutically useful tool in this book, readily understandable by any intelligent person with

a high school education. The clinician may recommend it to patients' families and friends with confidence. It will not take the place of case work or family therapy, but it will provide useful orientation.

The major clinical types, patterns of breakdown, and schizophrenic logic and language are all described in such a way as to invite empathy with the patient's experience while acknowledging the helpless distress of those close to him or her. There are vivid clinical examples throughout the book that throw a kindly and instructive light. The interplay of genetic, developmental, family, and social factors in producing a schizophrenic breakdown is presented fairly and lucidly. Dr. Arieti is sympathetic to the problems of the "nuclear family" in an urban society, writing nothing here that will needlessly burden already overburdened mothers and fathers. He nevertheless acknowledges the importance of inheritance and parenting.

One chapter on treatment emphasizes the combined use of psychotherapy and psychoactive drugs. Dr. Arieti explains what happens in the former and discusses the uses and limits of the latter. There is another chapter on hospital care in which the importance of a fully supportive milieu is emphasized. The indications for and against hospitalization are reviewed.

One might wish for a fuller discussion of ECT than Dr. Arieti gives us. Although it is not usually employed, it is sometimes lifesaving. Popular hostility to this measure would make a more explicit mention of its indications and safety desirable. I was also troubled by a statement on page 190: "I support the abolition of psychosurgery." Is there any other effective treatment for the rare but wretched individual completely imprisoned in a compulsive-obsessional system, unresponsive to psychotherapy, drugs, shock, or anything else?

The importance of early case finding and intervention is appropriately emphasized throughout, and supportive counseling for prospective parents is recommended when schizophrenia is present in a grandparent. There is an interesting chapter on "special situations" in which crises are discussed. Because it is all too true that "many psychiatrists are very reluctant to make home visits" the discussion mainly addresses the use of hospital emergency rooms and police. Dr. Arieti implies the importance of the therapist's immediate availability to the family when suicide or assault seems imminent, but he does not spell it out. This chapter also includes a discussion of the religious cult problem.

No book of such scope reduced to this length could satisfy every clinician, but this book is for families and friends. It should be useful to them and thereby helpful to schizophrenic patients and their psychiatrists.

The Psychodynamic Approach to Drug Therapy, *edited by Mortimer Ostow, M.D., Med.Sc.D. Riverdale, N.Y., Psychoanalytic Research & Development Fund, 1979, 344 pp., $18.50.*

In the introduction of this book the authors state, "Psychoanalysis can no longer afford to ignore organic treatment modalities, especially drug therapy." I agree. The contributors to this interesting volume have succeeded in describing how drug therapy can be effectively combined with in-depth psychoanalytic approaches in dealing with many difficult clinical problems. In the first part of the book an overview of clinical pharmacology, psychoanalytic psychiatry, and problems with the combination of the two are condensed and reviewed on the basis of the five cases that are presented in the remainder of the book.

The editor of the book, the individual participants, and a staff assistant have managed to condense into about 300 pages a monumental amount of case material and discussion without diluting or compromising their aims. Eight to twelve experts joined together eight or nine times per year for four years to review process case material of patients in psychoanalysis or psychoanalytic psychotherapy who also received psychoactive drugs. The case material is reported with day-to-day summaries and excerpts, and the group discussion of the participants is interspersed with the case material. In reading the material, I obtained a sufficient sense of the dynamics, the drug effects, and their interaction with each other to allow me to make observations of my own about the cases and to speculate on what was happening and how I might have intervened—psychotherapeutically and/or psychopharmacologically. The cases and discussion also allowed me to make valuable comparisons with my own clinical experiences.

This book suffers at least one serious shortcoming or disadvantage. The majority of the selected case material was taken from the early 1960s, when there was a limited experience with and selection of psychopharmacologically active drugs. Thus it is probably significant that it is not until the fifth and last treated case (spanning 1969–1971) that a more precise identification of target symptoms and corresponding selection of drug therapy is evident. The enabling power of a sophisticated, multimodality approach is most obvious in this case, where effective drug therapy combined with skillful ward management and sensitive psychoanalytic psychotherapy produced a remarkable and salutary treatment outcome.

All of the reported cases are about very sick patients. My reactions alternated between profound respect for the clinician's heroic efforts in treating such patients and uneasiness and impatience with what at times seemed more like trial and error approaches that produced more complications and side effects for the patient than benefits. In either event, this is a compelling book because the reader is afforded a very graphic opportunity to follow, over time, evocative and compelling case material. The reader also has a chance to witness the thoughtful (but at times, highly speculative) exchanges and discussions of a group of knowledgeable psychoanalyst/clinicians who are experienced in both psychoanalysis and psychopharmacology.

There is a tendency in this book to emphasize and focus on the unconscious meaning of the effects of drugs, motivational states, and the influences of psychoactive drugs on instinctual drives and to pay relatively little attention to the influences of ego and self structures and/or impairments to account for psychopathology and the effects of drug therapy. It is not surprising, then, that some of the participants in one of the group discussions provocatively (and I believe erroneously) conclude that one of the unsalutary consequences of symptom relief with drug therapy is that the patient often abandons treatment because he or she feels better. They offer that perhaps this is desirable from the public health/case reduction point of view but undesirable if one wishes to work

longer psychotherapeutically with such patients. I believe it is on a similar basis that they also conclude that drug therapy has little to offer in the management of personality disorders. I disagree that drugs reduce motivation for psychotherapy, and I also disagree that drug therapy has no place in the treatment of personality disorders.

When it is argued that drug treatment might cause premature termination of treatment, it could be argued equally strongly that our sicker patients' fears and distress about human contact and closeness drive them away from psychotherapy and that the permissive effect of psychotropic drugs often helps to keep affects optimal and in turn makes psychotherapeutic work more possible. Similarly, many of the observed behavioral problems associated with personality disorders are related to warded-off, painful affect states. As therapeutic interventions begin to contain behavioral expressions of personality disorders, it is not uncommon to observe the surfacing of depression, anxiety, and panic states, which are treatable with drug therapy, which may then further facilitate psychotherapy.

Although I disagree and find myself at variance with some of the emphases and conclusions of this book, I believe it represents a very important contribution and approach. The contributors to this volume have effectively drawn attention to and instructively described how drug therapy can be combined with psychoanalytic approaches. I would recommend and I believe others would welcome similar future efforts by the contributors to this book and others, with the expectation that even more meaningful insights and practical clinical help would be forthcoming given recent advances in psychoanalytic theory and technique and a more sophisticated appreciation of the action, use, and side effects of the many psychoactive agents we currently use in clinical practice.

Temperament Styles in Adult Interaction: Applications in Psychotherapy, *by Jane Burks, Ph.D., and Melvin Rubenstein, M.D. New York, N.Y., Brunner/Mazel, 1979, 205 pp., $15.00.*

Burks and Rubenstein present an approach to psychotherapy that is based on identification by the patient of his or her temperamental style and of its effects on his or her relationships. Their thesis, arising from the 20-year longitudinal study of temperament in children by Thomas, Chess, and Birch, is straightforward: temperament, a "biopsychological sub-system," is an inborn dimension of "reactivity and activity"; although influenced by family and social forces, it persists essentially unchanged throughout life and is an important determinant of behavior.

In their work with adult patients, the authors have identified six temperamental styles based on such characteristics as level of activity, mood, responsiveness, and adaptability. Thus the withdrawer is cautious, thorough, and realistic; the persister is intolerant of interruption and proud of his perfectionism; the intenser is forceful in his feelings and the way he expresses them; the approacher is quick to respond and adapt to new situations; the adapter is a pleasing person and easy to get along with; and the doer is highly active and preoccupied with achievement and success.

In therapy, the patient is made aware of his temperament through a process of self-identification (this is achieved in part by his completion of a simple questionnaire) and of its manifestations in various forms of relationship such as with parents, spouse, and workmates. The patient then comes to accept that his temperament is inherent and learns how to use it in his relationships, particularly by making it known to others. According to the authors' experience these goals are better achieved in group therapy than in individual therapy. The therapeutic approach also has application in family and marital therapy as well as in nonclinical settings.

This form of treatment, and the theory underlying it, are certainly replete with good common sense, but many therapists will no doubt find it overly schematic and some will even find it facile. The authors seem to concede this by emphasizing that temperament is only one aspect of personality and then not even the most important; yet their approach in practice appears to deny these additional aspects.

The book is irritatingly cluttered with jargon: manipulative intentionality, individuate, oppositionality, and occupational system are but a few examples. Although it is less than 200 pages long I also found it rather repetitive; for example, we read at several points about the immutability of temperament and about therapeutic goals.

SIDNEY BLOCH, PH.D.

The Family: Evaluation and Treatment, *edited by Charles K. Hofling, M.D., and Jerry M. Lewis, M.D. New York, N.Y., Brunner/Mazel, 1980, 313 pp., $17.50.*

This book contains the presentations given at the 1979 meeting of the American College of Psychiatrists; as such it is a mixed bag. In it are a number of absolutely first-rate papers containing material not available elsewhere and reflecting original thinking of a high caliber. Jerry M. Lewis' chapter, titled "The Family Matrix in Health and Disease," is a fine review of the systems approach to families and of his and his colleagues' own work. The chapter by David Reiss, "Pathways to Assessing the Family: Some Choice Points and a Sample Route," is outstanding both in its review of the current state of the diagnostic assessment of families and its discussion of the work of his group. For those who are not familiar with the sociobiological perspective on the family, the chapter by David P. Barash, "Evolutionary Aspects of the Family," is a good introduction.

Also in the book are a number of useful and sensible contributions that do not add to the field but review aspects of it. Theodore Lidz's summary of his thinking is one such, as is the sensible discussion of "family interviewing" as opposed to "family therapy" contributed by Saul L. Brown. Brown emphasizes that family interviews can contribute to a treatment program even if they are not the central therapeutic modality and how this can be accomplished. Similarly, the discussion of "The Family as a System" by James Grier Miller and Jessie L. Miller is a competent introduction to this approach to families.

Finally, there are in this volume a number of slighter contributions that may have been interesting as an introduction to family therapy and how to do it for the audience at the meeting. For instance, Marshall D. Schechter and Harold I. Lief discuss a case involving both family and marital treat-

ment that shows a high level of clinical competence. This chapter, "Indications and Contraindications for Family and Marital Therapy: An Illustrative Case," and several others like it do not add to our knowledge and will probably be of interest only to those who have read little or nothing in the field of the family.

The paper by Yrjö O. Alanen titled "In Search of the Interactional Origin of Schizophrenia" deserves separate comment. Alanen is a major contributor to our understanding of schizophrenic patients and their families. This chapter does not do his work justice, probably because he did not have enough time and space and because the issues in this field, where family influences and genetic endowment interact, are so complicated that they are not easily summarized. Alanen's chapter stands alone, somewhat out of place in the book because the current state of this area deserves both a comprehensive review and a clear exposition of Alanen's own work and views. This chapter accomplishes neither task while attempting both.

It is unclear for whom this book, and many like it, are intended. It is appropriate for neither the beginning student of the family nor for the advanced practitioner. Perhaps it belongs in libraries. The chapters by Lewis and Reiss added to my personal understanding and knowledge, and some of the chapters, such as the one by Brown, would be useful to give to residents beginning their work on an inpatient ward. It is unclear, however, that there are readers who will find most of this volume useful or interesting. Much of the book is redundant or available in better form elsewhere. For instance, Lidz should be read at greater length than the 20-some pages his chapter occupies, and Donald Bloch has much more to say than he does here.

In conclusion, editors of collections must be more exacting in whom they will and will not include in the final proceedings of a meeting because much of what sounds interesting in person is not valuable in print. They will also have to consider more carefully for whom the volume is intended.

HENRY GRUNEBAUM, M.D.
Cambridge, Mass.

Methods of Biobehavioral Research, *edited by E.A. Serafetinides, M.D., Ph.D. New York, N.Y., Grune & Stratton (Harcourt Brace Jovanovich), 1979, 213 pp., $19.50.*

Research in psychiatry suffers from many ills, not the least of which is the relative lack of emphasis on rigorous research training. The Seminars in Psychiatry series attempts to stimulate interest in biobehavioral research by publishing reviews and updates of the technical advances that are being made in various areas. As a volume in this series, *Methods of Biobehavioral Research* is intended to be an introduction to research methodology, a basic primer emphasizing definitions of terms and techniques and/or describing the rationale for a dozen different research areas. There is no special organization or logical sequence in the material offered (or for this particular selection), but the reader will have no difficulty discriminating between the "hard" and "soft" research areas—not only in terms of the useful information provided but in the extent to which they fulfill the ostensible goals of the volume.

The two opening chapters on neurobiochemistry by A. Yuwiler cover the basic methods of research in biochemistry and then provide an overview of neurochemical approaches in the diagnosis, treatment, and etiology of disease. W.J. Dixon deals with issues in the design of experiments and analysis of research data in a well-organized introductory lecture describing the content of a course in statistics. Dixon provides an excellent reading list covering general texts, mathematical statistics, data analysis, statistics in medical research, and publications in psychiatric research.

Oldenfeld contributes a highly readable review of the pros and cons of several neurodiagnostic procedures for evaluating organicity, emphasizing computerized tomography (CT scanning), the newest of the imaging techniques used for the investigation of brain function. "Methods in Electrophysiological Research" by R. Coger, A. Dymond, and E.A. Serafetinides discusses ongoing electrical activity in the CNS and peripheral measures of autonomic and skeletal muscle activity and includes a section on instrumentation in electrophysiology.

Although it is not a description of methods, Colby's chapter is an excellent statement of the goals, limitations, underlying concepts, and assumptions of computer simulation approaches to research in psychiatry. The chapter on psychopharmacology by Van Putten, May, and Jarvik is also not a discourse on methodology so much as a discussion that ranges from issues in the design of clinical pharmacologic research to the interpersonal interactions that are required to implement such interdisciplinary research. Rounding out the "hard" chapters is an introductory lecture by D. Shapiro dealing with the definitions of relevant features of psychophysiology and biofeedback research and their background in the study of conditioning phenomena.

The chapter on clinical and psychotherapeutic methods of research by M. Straker is a description of the problems of research and researchers in psychiatry. The author does, however, define and illustrate a variety of approaches, pointing out their strengths and weaknesses. The perspective of a biopsychosocial approach to research is offered by J. Cohen, and McGuire's chapter on ethological methods is actually devoted to a definition and justification of ethology. The chapters on family therapy by M. Lansky and nursing research by J. Messick contain some substantive material but also fail to address methodology as such.

In terms of subject matter and content, *Methods of Biobehavioral Research* is a heterogeneous collection of "introductory chapters." The editorial rationale for attempting to cover so much of biobehavioral research rather than devoting a volume to a single area of research is not clear. Personally, I would have preferred the latter. In some areas, of course, such introductory texts are available. There would seem to be a need for more extensive coverage in other areas, and, based on the content of some of these chapters, there are still other areas where there is not yet enough accumulated experience to have developed and evaluated methods and techniques appropriate to the phenomena of primary concern. Be that as it may, several of these chapters are excellent introductions to their respective subjects and are aimed, I would judge, at the novice or undergraduate student. They would make comprehensive introductory lectures summarizing the content of a course or seminar—and, I suspect, many of them are just that. However, there is often a need for just that! The professional investigator often finds it difficult to return to the most basic tenets of his or her approach. The serious beginner is likely to be sent someplace else for the basics in the methodology of the field in

which he or she may be interested. However, if this small volume does not provide everything, it may contain something you wanted to know about a particular area but were afraid to ask.

ROBERT ADER, PH.D.
Rochester, N.Y.

Mental Health Issues in Grief Counseling. Summary of Proceedings: National Conference on Mental Health Issues Related to Sudden Infant Death Syndrome, *edited by Stanley E. Weinstein, Ph.D. Rockville, Md., U.S. Department of Health, Education, and Welfare, 1979, 133 pp., no price listed (paper).*

Sudden infant death syndrome is a confrontation with the absurd. Most people have at least some cognitive awareness of their vulnerability, lack of control, and finitude, but at the same time, as parents they maintain a comfortable illusion that their infants can be loved, cradled, and protected from the world—and from death. If babies are not safe, who is? Sudden infant death syndrome is a violent cognitive and affective assault on the immortality fantasy of the parents. I recommend this collection of papers for all those who work with grief and loss in any form, and for both those who have an inkling of their own finitude and those who do not.

The conference on which this book is based offered experiences that stimulated both the minds and the feelings of the participants. George Engel involved his audience at the conference in a film made by the British Broadcasting Company on the Aberfan slag heap disaster in which 120 people were killed, most of them children. His chapter, titled "Teaching and Learning About Grief," is an affect-laden and instructive exchange between the conference participants and himself after they watched the film together. This and other contributions remind us that the catastrophe of sudden loss inspires anger and helplessness in those whose efforts to be of help seem puny when contrasted to the event.

Albert Cain contributes an excellent chapter on "The Impact of Sudden Infant Death on Families," and Lois Murphy offers another on "Early Attachments and the Effect of SIDS on Parents," particularly the mother. The severity of grief reactions and their enduring nature coupled with the ripple effect on other family members, even through the generations, is emphasized. Cain offers the timely reminder that the verbal, open, shared, and tearful expression of grief is not the one and only true way, and that territoriality often leads to helping people believe that they are the only ones with the knowledge and know-how required to be of help. Murphy points out that sudden infant death syndrome usually occurs in the first six months of life in a "honeymoon phase" during which many parents find their babies "pure joy." The parents experience the bewildering traumatic loss as loss of part of self. The loss of self-confidence, physical distress, guilt, anger, denial, emptiness, aloneness, and loss of meaning of life are all well described. Cain also emphasizes the need to give attention to siblings as well as to both parents.

The role of the counselor and the impact of the work on her or him receives attention in several papers, particularly those of Arthur Rosenbaum and George Engel. There is need for support from colleagues and for awareness that burnout will occur if there is a great imbalance in the counselor's life between giving and receiving. Rosenbaum gives many useful observations about the tasks of counseling, but his is not a "how to" chapter, which would be appropriate only if counseling were a technology rather than an art.

Donald Klein offers wisdom in "Selecting the Mental Health Consultant," and Michael Rothenberg summarizes the conference with great sensitivity. The spiritual dimension receives very little attention and needs to be included in any review of matters of life and death.

I wish that I had been at the conference to experience the affective components, but the 10 contributors have done a great service to us all in sharing their wisdom through the written word.

N. MICHAEL MURPHY, M.D.
Albany, N.Y.

Specialized Techniques in Individual Psychotherapy, *edited by Toksoz B. Karasu, M.D., and Leopold Bel'ak, M.D. New York, N.Y., Brunner/Mazel, 1980, 490 pp., $25.00.*

Twenty-two authors contribute 25 chapters focused on clinical case material that is bound to capture the interest of a wide variety of psychotherapists. Although each chapter is the product of an authority in the field, the final product reveals an uneven quality of excellence. The title led me to anticipate that the focus would be on the details of various strategies in psychotherapeutic activity. What is offered instead is a feast of interesting clinical situations, clinical problems, and diagnostic entities that provide opportunity to discuss recommended specific styles of psychotherapeutic intervention. The clinical entities include ambulatory schizophrenia, borderline personality, obsessive states, alcoholism, stress response syndrome, pathological mourning, sexual dysfunction, psychotherapy of the depressed patient, and others. Marmor (1) has pointed out that we must continue to strive toward a unified science of psychotherapy that will enable us to fit the patient, the therapist, and the technique together in a way that will most effectively, economically, and humanely achieve the desired objectives of mental health.

In the introductory overview, Dr. Karasu states that the task for the future is the achievement of greater specificity for particular kinds of intervention. In reviewing the current plethora of psychotherapies, he suggests three major topographies for clustering in relation to basic themes. These include the dynamic, behavioral, or experiential themes. He describes psychotherapy as a mutual therapist-patient endeavor to investigate and understand the nature of the patient's distress and for treatment of same. He points out that the therapeutic relationship is the dynamic balance between real object relationship, the therapeutic alliance, and transference, and he comments that a good clinician calibrates the use and the timing of the therapeutic techniques. Dr. Karasu also contributes a chapter dealing with the psychotherapy of the physically ill patient. He discusses the dynamic interactions between external stressors, characterological defenses, and coping problems and cautions that countertransference responses, which are reflected by premature confrontation, or interpretations about the patient's use of denial or affective blocking, are a major contributor to therapeutic failure in this clinical situation.

I found Dr. Kernberg's chapter on the psychotherapy of

borderline patients both interesting and helpful. The contribution by Dr. Horowitz on brief treatment of stress response syndromes is also excellent. The chapters on hypnotherapy, sexual therapy, the suicidal patient, the elderly patient, and ambulatory patients with severe anxiety are less successful. The latter article recommends the use of neuroleptics for severe neurotic anxiety and ambulatory ECT under related circumstances. These comments are not congruent with current concepts about somatic management of anxiety states.

Several chapters are unusual in that the topics concern common clinical conditions that somehow escape discussion. These include racial issues in psychotherapy (Hugh Butts, M.D.), family and marital therapy combined with individual therapy (Stephen Fleck, M.D.), and combined psychotherapy and pharmacotherapy (Gerald Sarwer-Foner, M.D.).

Throughout the book the major psychotherapeutic stance is provided by psychoanalytic and psychodynamic formulations. The flexible adaptive variations of this basic hypothesis are useful in providing an underlying theoretical and structural support for psychotherapeutic work in a wide variety of clinical settings. However, this book shares the shortcoming of many others on psychotherapy in that process is described but data on outcomes are lacking.

Whether the practitioner's interest lies in private practice, the general hospital, community clinic, or institutional psychiatry, this book provides good reading and useful clinical clues and can be a guide to better psychotherapy. The editors' hopes and objectives are fulfilled in this volume.

Nourishing the Humanistic in Medicine: Interactions with the Social Sciences, *edited by William R. Rogers and David Barnard. Pittsburgh, Pa., University of Pittsburgh Press in cooperation with the Institute on Human Values in Medicine of the Society for Health and Human Values, 1979, 325 pp., $10.95.*

We are in a time when the pertinence of the medical model to psychiatry is passionately defended and attacked. This volume usefully expands the definition of that model in directions that should somewhat mute the controversy over its applicability in psychiatry. Those who want psychiatrists to reidentify themselves with other physicians and medical practices will find it easier to persuade psychiatrists who see their role and skills as encompassing the pathogenic and therapeutic elements in society at large. Those who promote a broader, more varied view of illness, health, and the physician will find their dimensions more comfortably capacious as herein tailored.

The book insistently and correctly turns our attention to values, an area sadly neglected in medical and psychiatric education. Values, in my view, are the specific human adaptation device. That which works (to some end or other) becomes valued. Values become organized into value systems. Value systems then develop momentum and inertia, which may then foster or frustrate all human endeavor, especially the understanding of health and unhealth and provision for their care.

The tendency of both social scientists and physicians to subdivide their concerns and approaches into hyperspecialisms that ignore the needs of whole human beings is diligently and successfully countered by this book.

This group of essays by individual authors grew out of dialogues initiated by the Institute on Human Values in Medicine, partly funded by the National Endowment for the Humanities. The participants from medicine and social sciences were provided five two-day retreats over the course of two years in which to reflect, reveal, and stimulate one another's thinking, so the results are illumined by these efforts and opportunities for the contributions to affect one another before reaching outside readers. Particularly impressive to me in this imaginative plan to humanize was the exchange among participants about their personal and professional "pilgrimages," including encounters with tragedy, illness, medical care, and healing. This process, plus the debate and discussion by the group at preliminary presentations, lend the finished chapters a degree of integration and mutual honing uncommon in contributions to an edited volume.

Theologian/psychologist William B. Rogers competently reviews and interprets for medical educators the dual factors of helplessness and power as they are experienced, taught, and learned by doctors, patients, and society.

Psychiatrist Robert J. Lifton urges the replacement of what he calls "psychic numbing" and the "technicist" model of professional intervention with a renewed emphasis on value advocacy and personal openness in dealing with critical ethical questions in medical education.

Anthropologist Anthony Oliver-Smith sensitively examines the role of the fit between the basic assumptions of two parties in a "crisis dyad," trying to construct a helpful context of meaning for suffering.

These three papers contributed most to my understanding, but historian Barbara Sicherman's analysis of the cyclical nature of the "progressive" medicine propounded by Richard Putnam and Henry Cabot is also valuable, as are the other eight chapters.

All this being said, I found the book lacking in a credible unifying view of humankind that would optimize the utility of other concepts presented. The role of intraspecific cooperation in the survival and well-being of all species, particularly our own, should have been prominently underscored. Some such humanizing formulation as that of Ashley Montagu should have been incorporated: the purpose of human life is to live as though to live and love were the same thing.

That the authors have nevertheless been faithful latently to such understanding is revealed by my wish to have been present in order to more explicitly give it tongue.

Adaptation in Schizophrenia: The Theory of Segmental Set, *by David Shakow, Ph.D. New York, N.Y., Wiley-Interscience (John Wiley & Sons), 1979, 232 pp., $19.95.*

Ever since his early days as Chief Psychologist and Director of Psychological Research at the Worcester State Hospital, David Shakow has been interested in schizophrenia as a

clinician and as a researcher. When he writes on the subject, therefore, it behooves us to listen. The present volume sets forth his theory of segmental set. Generalized set is described as "the kind of adjustment (conscious, preconscious, and unconscious) that disposes a person to perceive a situation objectively and to respond equally objectively, in an autonomous fashion." Segmental set typical of schizophrenia "is disclosed by an inconsistency within an aspect of the response (as in cognitive dispersal) or in the incongruous combination of the cognitive, affective, and conative aspects into a spontaneous unit." The result is schizophrenic thinking.

Shakow draws heavily on his earlier work at Worcester and later at NIMH. As he states in his preface, he eschews the ideal task of integrating the enormously complex body of clinical and experimental literature bearing on the subject. The result is a somewhat disappointing volume that gives the impression at times of being thrown together hastily without adequate reference to the other literature, particularly of the later decades.

The book is introduced by a well-deserved tribute to Shakow from his colleague David Rosenthal. The beginning chapters on set theory and on the stimulus-response process that serves as context for it are clear and explicit, although one regrets Shakow's frank avoidance of any detailed integration of set theory with modern psychopharmacology, linguistics, decision theory, and cognitive psychology. There follow, however, a series of brief 3–5-page chapters on research, developmental aspects, coping behavior, symptoms, and diagnosis that promise more than they fulfill. The 3-page treatment of developmental aspects (actually about 2 pages of text) might better have been left out. The 5-page chapter on the therapeutic aspects of segmental set has little that is new and specific to set theory.

The relative neglect of the background of the set concept in history is corrected by an appendix by Ann Masten on "Set and Schema Theory in Twentieth Century American and British Psychology," which, however, relates to Shakow's work only incidentally. The appendix also has a 21-page description of the Worcester State Classification System for Schizophrenics, which although interesting in the light of the appearance of *DSM-III* is of little pertinence to the explanation of set theory. In summary, Shakow has much to offer in his clinical-descriptive treatment of segmental set but is disappointing in his theoretical and integrative development of it.

The volume has a detailed author and subject index and an adequate bibliography.

Chicago, Ill.

Basic Intensive Psychotherapy, *by William H. Reid, M.D. New York, N.Y., Brunner/Mazel, 1980, 126 pp., $12.00.*

This succinct, clearly written book is specifically aimed at all beginning psychotherapists and their supervisors, not only residents in psychiatry. It has a strong psychoanalytic bias (for instance, the phenomena of psychic energy and ego defense mechanisms are repeatedly dealt with).

In his preface Dr. Reid explicitly hopes to follow in the tradition of Dr. Kenneth Colby's *Primer for Psychotherapists* (1). He succeeds admirably in this ambitious task.

The book deals with everyday realities and problems encountered in intensive psychotherapy, both those of the patient and those of the therapist. Most of the book deals with three distinct phases of therapy: 1) the opening phase, including building the therapeutic alliance, 2) the middle phase, dealing with resistance, working through, transference, countertransference, and specific psychotherapeutic techniques, and 3) the third phase, termination.

The longest section is that on the crucial middle phase of therapy. It deals with the actual, often painful and difficult work done to minimize the patient's symptoms. Dr. Reid discusses "the two basic forms" the transference may take—"a source of nourishment and love . . . or a figure of considerable authority." Working with important resistances, such as repression, projection, and denial, is discussed briefly and with a minimum of jargon.

The section on termination is especially helpful in its ideas about different types of termination—natural, forced, and premature. Trainees need much help in dealing with these issues and the guilt often stirred up within the therapist when he or she rotates onto another service and must terminate or transfer patients.

Scattered throughout the book are brief clinical vignettes dealing with the process of treatment and various therapeutic techniques. The book might be strengthened by increasing the frequency and length of excerpts from interviews, along with more examples and discussion of poor or inappropriate therapeutic interventions.

Overall, however, this book achieves its goal of briefly presenting basic concepts of psychodynamic, psychoanalytically oriented psychotherapy. The author's implicit skills as a therapist and supervisor make it a welcome addition to the literature. I recommend it to beginning therapists and their supervisors as a valuable aid in learning how to approach this subtle and fascinating form of psychotherapy.

Schizophrenia: A Biopsychosocial Perspective, *by Andrew Crider. Hillsdale, N.J., Lawrence Erlbaum Associates (New York, N.Y., Halsted Press, John Wiley & Sons, distributor), 1979, 194 pp., $16.50.*

This small volume is of interest to psychiatrists because it condenses and evaluates major up-to-date research and concepts of schizophrenia. Most valuable is the use of bridging concepts between descriptive psychiatry, biochemistry, genetics, and previous life history to arrive at a plausible amalgamation.

The book opens with a brief overview of changing concepts of schizophrenia from Bleuler and Kraepelin through *DSM-III*, including the problems that still remain in making a reliable clinical diagnosis of schizophrenia.

The second chapter, "The Schizophrenic Psychosis," amply illustrates the author's view of the development of the schizophrenic psychosis from its onset, marked by a mood shift toward euphoria, to early schizophrenia, marked by in-

creased perplexity because of the inability to control attention and ideation. This is followed by the schizophrenic psychosis, complete with primary and secondary delusions, hallucinations, a language disorder, and a variety of dissociative phenomena characteristic of the full-blown psychosis. The author supports these three phases by a much needed summary and synthesis of well-known research studies on reaction time and attention dysfunction.

The third chapter, on major biochemical hypotheses, is well suited for students of psychiatry and includes a parsimonious presentation of the way neurotransmitters function at synapses. The transmethylation hypothesis, the dopamine hypothesis, and the amphetamine hypothesis are clearly presented, as is the evidence for and against each. The section on the orthomolecular hypothesis at best provides a basis for refuting the outrageous pseudoscientific claims made for this approach. It is unfortunately given too much space for its importance. More important, Crider makes it abundantly clear that any single biochemical model at this time cannot be definitive because of the vast complexity of the brain and the possibility that there are myriad unknown and only partially known biochemical processes remaining to be studied.

In the economical review of genetic factors in schizophrenia, the fourth chapter, the author tends to prefer the polygenic over the modified dominance inheritance theory. He concludes that inherited predisposition is necessary but not sufficient to produce schizophrenia and reasons that genetic studies provide the best single source of evidence for the role of environmental factors in its etiology.

The chapter on life history contains a tightly reasoned review of three major retrospective developmental studies and illuminates the scientific limitations to their findings as having significance in the etiology of schizophrenia. In a similar way, Crider finds that predictive studies on high-risk populations are faced with very complex problems of selection of subjects, diagnostic criteria, and the number of decades necessary to do such a study.

In the section on developmental studies the author concludes that both uncontrolled clinical observations and controlled laboratory studies of interactions and communication patterns of families with schizophrenic children fail to demonstrate a specific developmental or life history event that characterizes preschizophrenic children or that can be isolated as being necessary for later psychosis.

The chapter on patienthood deals with the social impact of schizophrenia as demonstrated by epidemiological studies and includes the significant demographic correlates of socioeconomic status, age, and race. The next section sketches the decline of the mental hospital as the primary place to treat psychotic patients. The section on deinstitutionalization and patient care summarizes the mental health legislation, the litigation regarding human rights of mental patients, and the role of antipsychotic medications in the development of patient care in the community.

The book closes with a knowledgeable survey of the unfulfilled promises of deinstitutionalization and the myth of rehabilitation, the myth of reintegration, and the myth of continuity of care. Except for a few small sections meant for students this is an excellent review of schizophrenia fo psychiatrists.

ıe question of dependence and tolerance

What does the scientific literature say about ese drugs causing physical or psychological depen- nce? Is tolerance a genuine problem?

John Marks, M.D., Fellow and Director of Medi- l Studies of Girton College, Cambridge (England) s reviewed the enormous worldwide medical litera- e on the benzodiazepines to determine whether d to what extent dependency and tolerance are ported problems with these agents. His findings, lineated in a new monograph, are quite enlighten- g. And their practical implications are further plored in a videotaped interview with Dr. Marks that ur local Roche representative will be pleased to ow to you and your staff or organization.

To obtain a copy of Dr. Marks' important mono- aph highlighting his findings or a showing of his inter- w, complete the coupon on the right and mail to:

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associateo with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

Wyeth Laboratories
Philadelphia, PA 19101

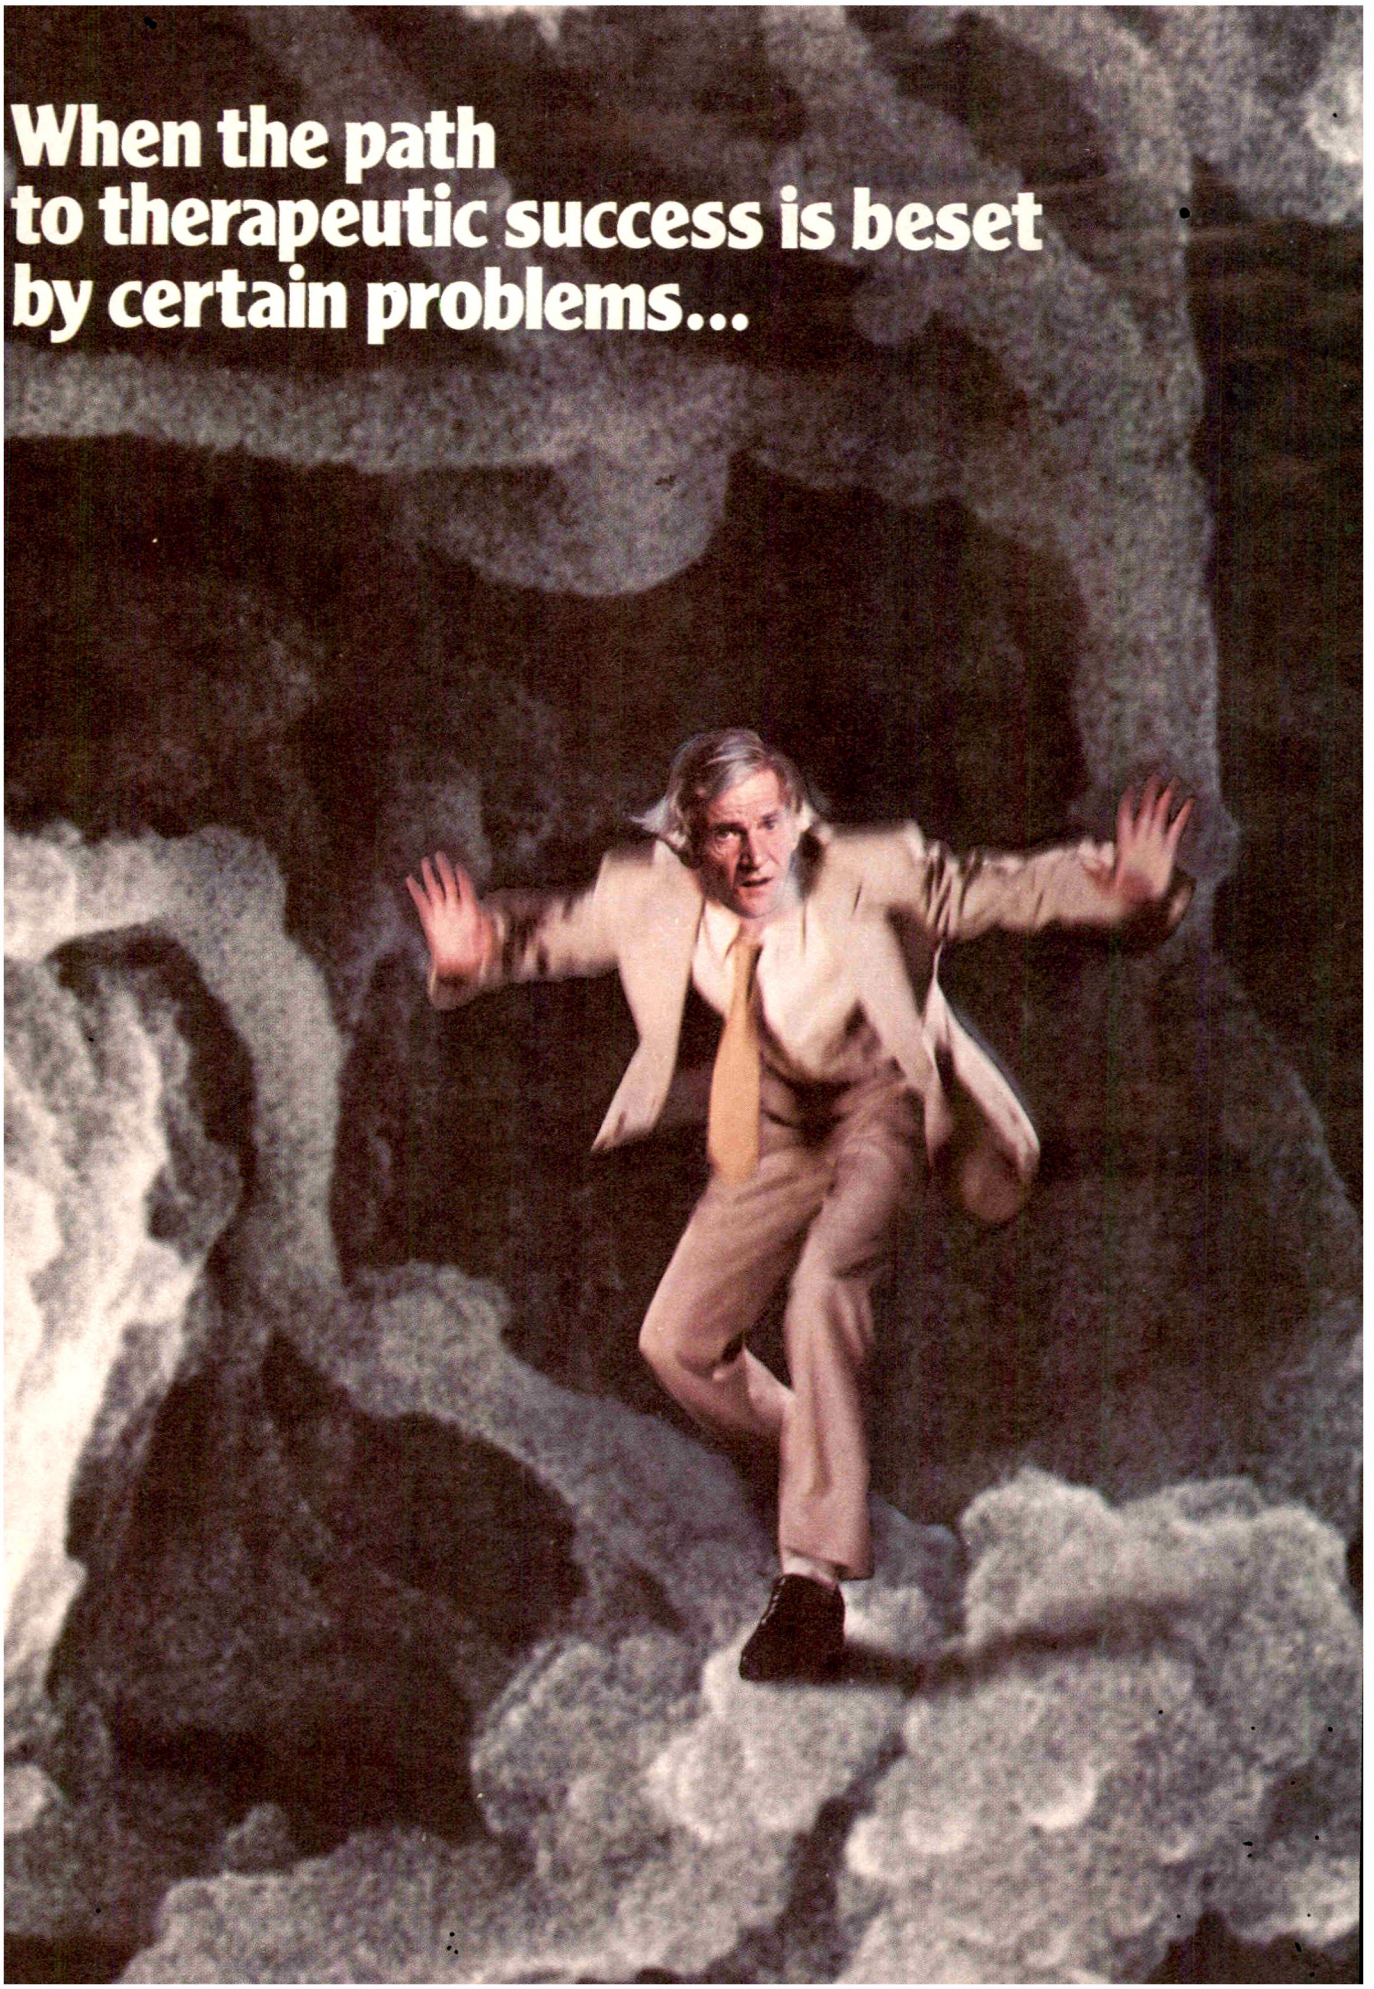
An age for anxiety.

The aging process all too frequently is accompanied by anxiety states. When anxious older patients do not respond to your sympathetic counseling, a benzodiazepine may be the next logical step.

But which one? Here, more than in many other patient groups, the metabolites of the available compounds may make a decisive difference. Unlike diazepam, clorazepate and chlordiazepoxide, Ativan (lorazepam) has no long-acting metabolites, and its simple metabolism is less readily impaired with advancing age. Steady-state serum levels are rapidly achieved and disappear rapidly once you decide to discontinue therapy. For these reasons, residual effects are not likely to present problems. (The pharmacokinetic profile of a drug can define such characteristics as its absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Proved effective in many nationwide, double-blind studies (including patients in older age groups), Ativan is compatible with a wide range of commonly prescribed drugs. (The benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.) Patients who have trouble swallowing solid medication appreciate the small Ativan tablet, which is tasteless and disintegrates within seconds in water or fruit juice.



See important information on preceding page.

Ativan® (lorazepam) C IV

0.5 mg tablet

for Anxiety

When the path
to therapeutic success is beset
by certain problems...

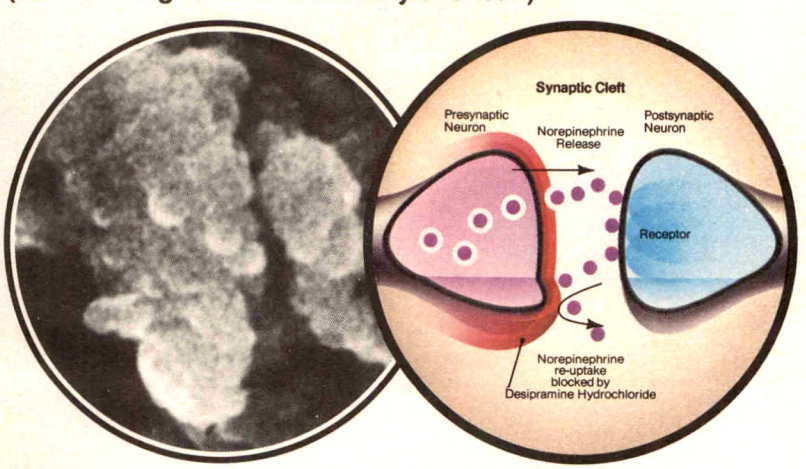
Start antidepressant therapy with

Norpramin®

(desipramine hydrochloride tablets NF)

25, 50, 75, 100, 150 mg.

to ease the patient's path



Helps relieve the sleep disturbances that often accompany depression.

- Improvement in sleep patterns may begin within one week in some patients.[1]
- As the depression is relieved, difficulty in falling asleep, restlessness, and early morning awakening diminish.
- The patient is helped to remain calm yet active, although the physician should caution the patient about driving or operating machinery if drowsiness occurs. (See Warnings, Precautions, and Adverse Reactions overleaf.)

Less anticholinergic activity

- Studies of animal tissues[2] and normal human subjects[3,4] have shown that desipramine has less anticholinergic activity than amitriptyline or doxepin.
- The single-bond side chain of desipramine may be associated with less anticholinergic activity than is the double-bond side chain of amitriptyline or doxepin.
- This may mean less dry mouth, less blurred vision, less urinary retention, less constipation.

(See Warnings in Brief Summary overleaf.)

Electron micrograph of human synaptic cleft, postulated site of tricyclic antidepressant activity.

Laboratory evidence suggests that desipramine blocks the re-uptake of norepinephrine at the presynaptic nerve terminal,[7] ensuring increased cleft and receptor site neurotransmitter concentration.

Potent blocker of norepinephrine re-uptake

Current evidence[5,6] suggests depression results from inadequate levels of norepinephrine or serotonin here, at the synaptic cleft.

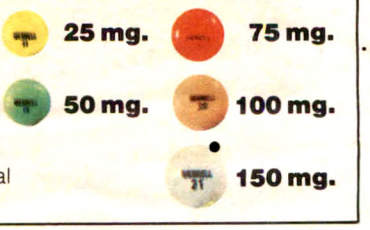
If your patient is unresponsive to treatment with one tricyclic, consider switching to a tricyclic that blocks the re-uptake of a different neurotransmitter.

(Please read the Brief Summary overleaf before prescribing Norpramin.)

Merrell

MNQ-264

A-40



☐ Norpramin offers improved sleep patterns beginning within one week in some patients.

☐ Norpramin provides less anticholinergic activity than amitriptyline or doxepin, as shown in studies of animal tissues and normal human subjects. (See Warnings section of Brief Summary.)

☐ Norpramin is a potent blocker of norepinephrine re-uptake.

Dosage Flexibility

Convenient choice of 5 tablet strengths and once daily or divided dosage schedule allows titration to individual response.

Norpramin®
(desipramine hydrochloride tablets NF)

AVAILABLE ONLY ON PRESCRIPTION

Brief Summary

MECHANISM OF ACTION: Available evidence suggests that many depressions have a biochemical basis in the form of a relative deficiency of neurotransmitters such as norepinephrine and serotonin. Norepinephrine deficiency may be associated with relatively low urinary 3-methoxy-4-hydroxyphenyl glycol (MHPG) levels, while serotonin deficiencies may be associated with low spinal fluid levels of 5-hydroxyindolacetic acid.

While the precise mechanism of action of the tricyclic antidepressants is unknown, a leading theory suggests that they restore normal levels of neurotransmitters by blocking the re-uptake of these substances from the synapse in the central nervous system.

Evidence indicates that the secondary amine tricyclic antidepressants, including Norpramin, may have greater activity in blocking the re-uptake of norepinephrine. Tertiary amine tricyclic antidepressants, such as amitriptyline, may have greater effect on serotonin re-uptake.

Norpramin (desipramine hydrochloride) is not a monoamine oxidase (MAO) inhibitor and does not act primarily as a central nervous system stimulant. It has been found in some studies to have a more rapid onset of action than imipramine. Earliest therapeutic effects may occasionally be seen in 2 to 5 days, but full treatment benefit usually requires 2 to 3 weeks to obtain.

INDICATIONS: Norpramin (desipramine hydrochloride) is indicated for relief of symptoms in various depressive syndromes, especially endogenous depression.

CONTRAINDICATIONS: Desipramine hydrochloride should not be given in conjunction with, or within 2 weeks of, treatment with an MAO inhibitor drug; hyperpyretic crises, severe convulsions, and death have occurred in patients taking MAO inhibitors and tricyclic antidepressants. When Norpramin (desipramine hydrochloride) is substituted for an MAO inhibitor, at least 2 weeks should elapse between treatments. Norpramin should then be started cautiously and should be increased gradually.

The drug is contraindicated in the acute recovery period following myocardial infarction. It should not be used in those who have shown prior hypersensitivity to the drug. Cross sensitivity between this and other dibenzazepines is a possibility.

WARNINGS: **1.** Extreme caution should be used when this drug is given in the following situations: a. In patients with cardiovascular disease, because of the possibility of conduction defects, arrhythmias, tachycardias, strokes, and acute myocardial infarction. b. In patients with a history of urinary retention or glaucoma, because of the anticholinergic properties of the drug. c. In patients with thyroid disease or those taking thyroid medication, because of the possibility of cardiovascular toxicity, including arrhythmias. d. In patients with a history of seizure disorder, because this drug has been shown to lower the seizure threshold. **2.** This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. **3.** USE IN PREGNANCY: Safe use of desipramine hydrochloride during pregnancy and lactation has not been established; therefore, if it is to be given to pregnant patients, nursing mothers, or women of childbearing potential, the possible benefits must be weighed against the possible hazards to mother and child. Animal reproductive studies have been inconclusive. **4.** USE IN CHILDREN: Norpramin (desipramine hydrochloride) is not recommended for use in children since safety and effectiveness in the pediatric age group have not been established. **5.** The patient should be cautioned that this drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. **6.** In patients who may use alcohol excessively, it should be borne in mind that the potentiation may increase the danger inherent in any suicide attempt or overdosage.

PRECAUTIONS: **1.** It is important that this drug be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with this class of drug. Ordinary prudence requires that children not have access to this drug or to potent drugs of any kind; if possible this drug should be dispensed in containers with child-resistant safety closures. Storage of this drug in the home must be supervised responsibly. **2.** If serious adverse effects occur, dosage should be reduced or treatment should be altered. **3.** Norpramin (desipramine hydrochloride) therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates. **4.** The drug may cause exacerbation of psychosis in schizophrenic patients. **5.** Close supervision and careful adjustment of dosage are required when this drug is given concomitantly with anticholinergic or sympathomimetic drugs. **6.** Patients should be warned that while taking this drug their response to alcoholic beverages may be exaggerated. **7.** Clinical experience in the concurrent administration of ECT and antidepressant drugs is limited. Thus, if such treatment is essential, the possibility of increased risk relative to benefits should be considered. **8.** The sedative effects of Norpramin and benzodiazepines (*e.g.*, chlordiazepoxide or diazepam) are additive. Both the sedative and anticholinergic effects of the major tranquilizers are additive to those of Norpramin. **9.** This drug should be discontinued as soon as possible prior to elective surgery because of the possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients taking desipramine hydrochloride. **10.** Both elevation and lowering of blood sugar levels have been reported. **11.** Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathologic neutrophil depression. **12.** Norpramin 25, 50, 75, and 100 mg. tablets contain FD&C Yellow No. 5 (tartrazine), which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS: NOTE: Included in the following listing are a few adverse reactions that have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when Norpramin (desipramine hydrochloride) is given.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke.

Psychiatric: confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurologic: numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus.

Anticholinergic: dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis, increased intraocular pressure; constipation, paralytic ileus; urinary retention, delayed micturition, dilatation of urinary tract.

Allergic: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs.

Hematologic: bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue.

Endocrine: gynecomastia in the male, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels.

Other: jaundice (simulating obstructive), altered liver function; weight gain or loss; perspiration, flushing; urinary frequency, nocturia; parotid swelling; drowsiness, dizziness, weakness and fatigue, headache; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

DOSAGE AND ADMINISTRATION: Not recommended for use in children. Lower dosages are recommended for elderly patients and adolescents. Lower dosages are also recommended for outpatients compared to hospitalized patients, who are closely supervised. Dosage should be initiated at a low level and increased according to clinical response and any evidence of intolerance. Following remission, maintenance medication may be required for a period of time and should be at the lowest dose that will maintain remission.

Usual Adult Dose: The usual adult dose is 100 to 200 mg. per day. In more severely ill patients, dosage may be further increased gradually to 300 mg./day if necessary. Dosages above 300 mg./day are not recommended.

Dosage should be initiated at a lower level and increased according to tolerance and clinical response.

Treatment of patients requiring as much as 300 mg. should generally be initiated in hospitals, where regular visits by the physician, skilled nursing care, and frequent electrocardiograms (ECG's) are available.

The best available evidence of impending toxicity from very high doses of Norpramin is prolongation of the QRS or QT intervals on the ECG. Prolongation of the PR interval is also significant, but less closely correlated with plasma levels. Clinical symptoms of intolerance, especially drowsiness, dizziness, and postural hypotension, should also alert the physician to the need for reduction in dosage. Plasma desipramine measurement would constitute the optimal guide to dosage monitoring.

Initial therapy may be administered in divided doses or a single daily dose.

Maintenance therapy may be given on a once-daily schedule for patient convenience and compliance.

Adolescent and Geriatric Dose: The usual adolescent and geriatric dose is 25 to 100 mg. daily.

Dosage should be initiated at a lower level and increased according to tolerance and clinical response to a usual maximum of 100 mg. daily. In more severely ill patients, dosage may be further increased to 150 mg./day. Doses above 150 mg./day are not recommended in these age groups.

Initial therapy may be administered in divided doses or a single daily dose.

Maintenance therapy may be given on a once-daily schedule for patient convenience and compliance.

OVERDOSAGE: See prescribing information for a discussion of symptoms and treatment of overdose.

Order Your Copy of the 1980 Membership Directory Now!

The latest listing of APA members (as of January 31, 1980) has just been published. Unlike previous editions, the 1980 Membership Directory, largely at the urging of President Dr. Donald G. Langsley, contains telephone numbers as well as names, addresses, membership class and membership status. A new format provides easy access to the alphabetical and geographical listings.

Another new addition to this Directory is a section containing the names and addresses of District Branch Executive Secretaries. Also included in this Directory is a list of Officers, the Board of Trustees and the Assembly, as well as past APA meetings, past Officers, Honorary and Distinguished Fellows and a membership table. This publication will provide readers with information about the APA and the most comprehensive listing of the membership since the 1977 Biographical Directory.

April 1980. Approximately 300 pages. Order #151. $13.00.

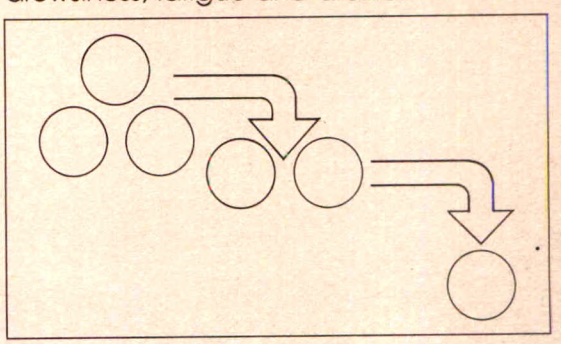
Fast-in

24-hour blood level curve of 10-mg oral dose of diazepam in a single healthy subject.



Smooth-out

Smooth: Avoids sudden symptom breakthrough Because of its fast and complete absorption, peak blood levels of Valium (diazepam/Roche) are achieved in 60 to 90 minutes after a single dose for a rapid initial calming effect. Typically, with an appropriate dosage regimen (e.g., 5 mg *t.i.d.*) Valium builds in a uniform and predictable way to a steady-state level within 5-7 days, without accumulating beyond. With Valium the excretion rate is similarly consistent and predictable. When pharmacologic support is no longer needed, the overlapping half-lives of diazepam and its metabolites insure a gradual elimination process. Because metabolites of short-acting benzodiazepines are inactive, blood levels of these drugs decrease more rapidly without benefit of a tapering effect.

Consistent therapeutic effect even when an occasional dose is omitted Once steady-state is achieved, sudden symptom breakthrough is highly unlikely, even if a dose is forgotten or skipped. That's because the half-life of Valium—27-37 hours—provides the advantage of self-tapering action, complementing your gradual reduction of the patient's dosage and smoothing his transition to independent coping.

To discontinue smoothly... Gradual discontinuation of medication—while rarely necessary after short-term therapy—*is* good medical practice in patients who have received high doses for extended periods. When dosage is tapered, untoward side effects can be avoided. Throughout therapy, in fact, side effects are infrequent with Valium and are seldom more serious than drowsiness, fatigue and ataxia.

Before prescribing, please see summary of product information on following page. ROCHE®

2-mg, 5-mg, 10-mg scored tablets

Valium®

Smooth transition to independent coping

diazepam/Roche®

Valium®
diazepam/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Management of anxiety disorders, or short-term relief of symptoms of anxiety; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

***Usage in Pregnancy:* Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension; changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam/Roche) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available in trays of 10.

He has five years to fight for your life

He is an American Heart Association Established Investigator, funded for five years to work on some phase of cardiovascular disease. He and his associates are researching ways to recognize a heart attack before severe damage occurs.

His ultimate goal is to decrease the present toll from cardiovascular diseases. Of the four Americans that die every minute this year from all causes, two will die from these diseases.

He is one of over 1,400 scientists supported by the American Heart Association who are fighting for your life.

But we need more money for more research that may produce earlier detection and better methods of treatment and prevention of cardiovascular diseases.

When a Heart Association volunteer asks for your money, think of the 1,400 scientific investigators. Help them fight for your life.

Please give generously to the
American Heart Association

WE'RE FIGHTING FOR YOUR LIFE

The American Psychiatric Association
Introduces

An essential program for clinicians learning to incorporate and utilize DSM-III

THE DSM-III INSTITUTIONAL INSTRUCTION KIT

THE DSM-III INSTITUTIONAL INSTRUCTION KIT acquaints physicians and their staff with:

- the multiaxial evaluation method used to report the official DSM-III diagnosis
- the use of new diagnostic categories in making a differential diagnosis
- the use of criteria as guides in making psychiatric diagnosis for the most significant disorders in:

Affective Disorders
Schizophrenia and Related Psychotic Disorders
Anxiety, Dissociative, and Somatoform Disorders
Personality Disorders
Disorders Usually Arising in Childhood or Adolescence

PROGRAM COMPONENTS:
The Instructor's Kit for workshop leaders contains:

- videotape of nine clinical case simulations
- loose-leaf binder containing:
  - — 4 audiocassettes plus transcripts of original faculty presentations
  - — 39 slides complementing audiotaped presentations
  - — course syllabus, patient histories, worksheets, references
  - — DSM-III diagnosis for each of 30 patient histories

The Participant's Kit for individual workshop members includes:

- course syllabus
- patient histories
- worksheets

CONTINUING MEDICAL EDUCATION (CME) CREDIT:
These learning materials can be used by educational organizations or institutions in the development of, or as an adjunct to, a variety of learning programs for CME Category 1, 2, or 5.

Artist Leonard Leff uses sculpture to express the painful depression he once experienced. He remembers it as "a lowering of the flame of life. My energies ebbed, my will to live decreased, and I found myself retreating from the activities of life to a more introverted existence."

Now available from ROERIG

WHEN DEPRESSION EXPRESSES ITSELF

SINEQUAN®
(DOXEPIN HCl)

ANTIDEPRESSANT EFFECTIVENESS with convenient once-a-day *h.s.* dosage*

150-MG CAPSULE†

Also available in:
100-mg, 75-mg, 50-mg, 25-mg, 10-mg CAPSULES and ORAL CONCENTRATE, 10 mg/ml, in 120-ml (4-oz) bottles

*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.

† The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

ANTIDEPRESSANT EFFECTIVENESS

SINEQUAN®
(DOXEPIN HCl)

150-mg CAPSULE*

CONVENIENT ONCE-A-DAY *h.s.* DOSAGE

which may improve patient compliance. The total daily dosage, up to 150 mg per day, may be given on a once-a-day schedule without loss of effectiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per day.

PROMINENT SEDATIVE EFFECT

which may help to relieve the difficulty in falling and staying asleep, and the early-morning awakening often associated with depression.

ESTABLISHED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accompanies clinical depression.

USUALLY WELL TOLERATED

At doses up to 150 mg per day, Sinequan does not generally affect the antihypertensive activity of guanethidine and related compounds. Tachycardia and hypotension have been reported occasionally. Drowsiness is the most commonly observed side effect. Dry mouth, blurred vision, constipation and urinary retention have been reported.

EXTENDED RANGE OF DOSAGE STRENGTHS

for flexibility in individualizing therapy.

*The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. These disorders should be ruled out, particularly in older patients. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN (doxepin HCl) in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Usage with Alcohol: It should be borne in mind that alcohol ingestion may increase the danger inherent in any intentional or unintentional SINEQUAN overdosage. This is especially important in patients who may use alcohol excessively.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy. Prescriptions should be written for the smallest feasible amount.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate severity, a starting daily dose of 75 mg is recommended. Dosage may subsequently be increased o decreased at appropriate intervals and according to individual response. The usual optimum dose range is 75 mg/day to 150 mg/day.

In more severely ill patients higher doses may be required with subsequent gradual increase t 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding a dose of 300 mg/day.

In patients with very mild symptomatology or emotional symptoms accompanying organic disease, lower doses may suffice. Some of these patients have been controlled on doses as lov as 25-50 mg/day.

The total daily dosage of SINEQUAN (doxepin HCl) may be given on a divided or once-a-da dosage schedule. If the once-a-day schedule is employed the maximum recommended dose i 150 mg/day. This dose may be given at bedtime. **The 150 mg capsule strength is intended fo maintenance therapy only and is not recommended for initiation of treatment.**

Antianxiety effect is apparent before the antidepressant effect. Optimal antidepressant effec may not be evident for two to three weeks.

Overdosage.

A. Signs and Symptoms

1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.

2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias an tachycardias.

Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ileus) hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.

B. Management and Treatment

1. Mild: Observation and supportive therapy is all that is usually necessary.

2. Severe: Medical management of severe SINEQUAN overdosage consists of aggressive supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautions t prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absorbed The use of activated charcoal has been recommended, as has been continuous gastric lavage with saline for 24 hours or more. An adequate airway should be established in comatose patient and assisted ventilation used if necessary. EKG monitoring may be required for several days since relapse after apparent recovery has been reported. Arrhythmias should be treated with th appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and CNS symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow intra venous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmine i rapidly metabolized, the dosage should be repeated as required. Convulsions may respond t standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depres sion. Dialysis and forced diuresis generally are not of value in the management of overdosag due to high tissue and protein binding of SINEQUAN.

Supply. SINEQUAN is available as capsules containing doxepin HCl equivalent to: 10 mg, 75 mg and 100 mg doxepin: bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). 25 mg an 50 mg doxepin: bottles of 100, 1000, 5000, and unit-dose packages of 100 (10 x 10's). 150 m doxepin: bottles of 50, 500, and unit-dose packages of 100 (10 x 10's). SINEQUAN Ora Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calibrate at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Each ml contains doxepin HCl equivalent to 10 m doxepin. Just prior to administration, SINEQUAN Oral Concentrate should be diluted wit approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prune o pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a number o carbonated beverages. For those patients requiring antidepressant therapy who are o methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be mixe together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not wit grape juice. Preparation and storage of bulk dilutions is not recommended.

More detailed professional information available on request.

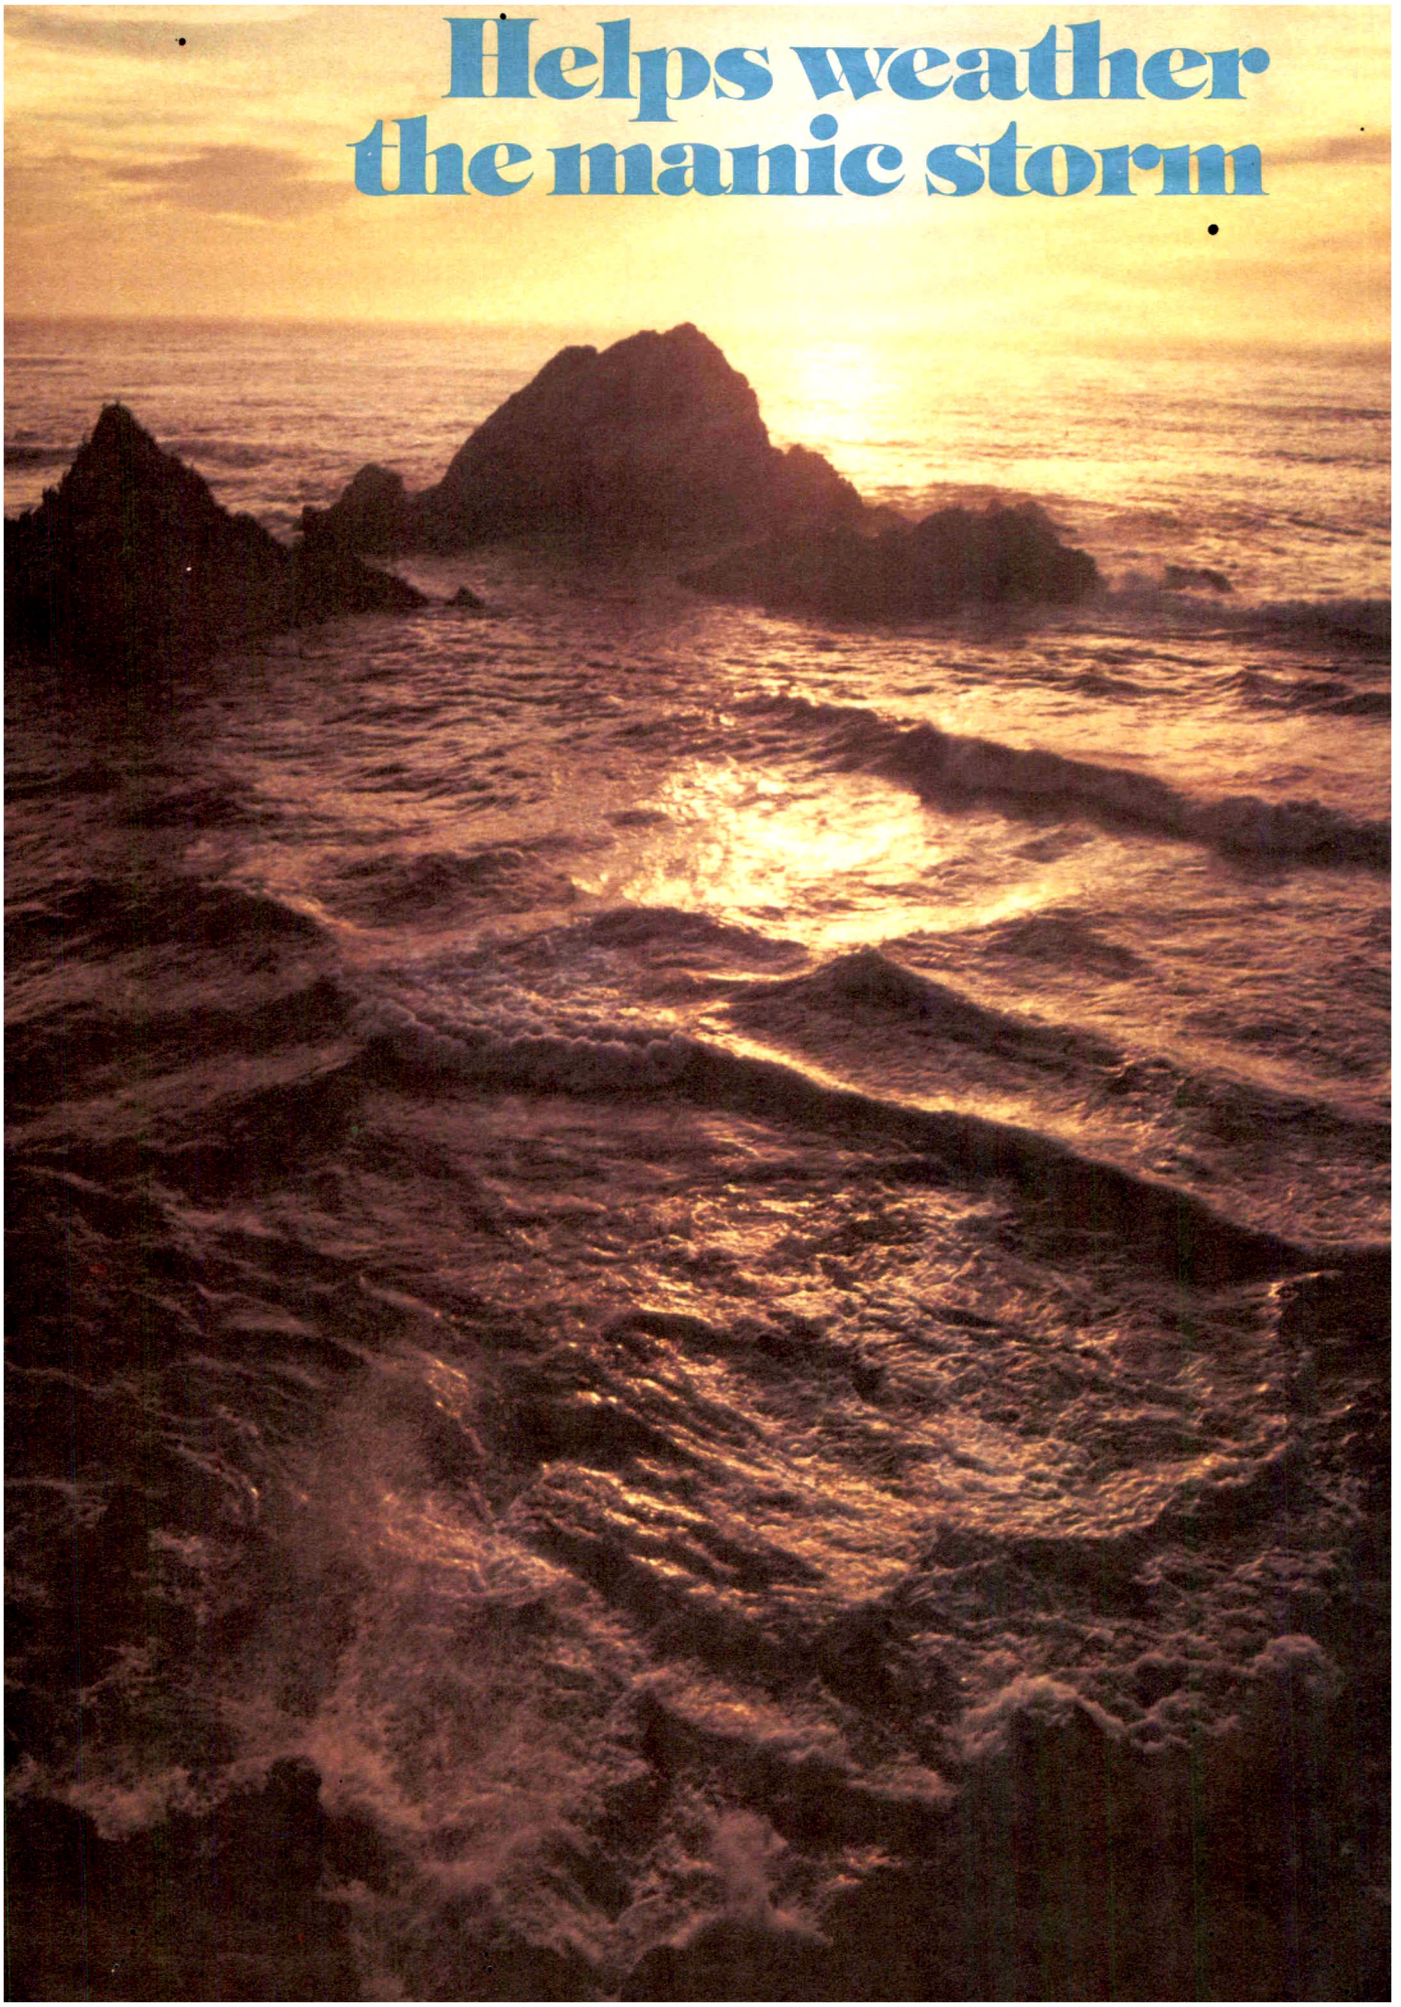
Psychiatric Associateships at National Institute of Mental Health

The National Institute of Mental Health Associate Program at the National Institutes of Health offers Associateships for two or three years of intensive training in virtually all areas of clinical and basic psychobiological research in adult and child psychiatry. Excellent facilities are available at the Clinical Center on the 306 acre NIH campus in Bethesda, Maryland, and at nearby St. Elizabeths Hospital in Washington, D.C. During the first year, Clinical Associates usually are assigned clinical responsibility for adults or children who are admitted for both therapeutic and research purposes; in the second and subsequent years they usually work full time on clinical or research projects, according to their interests. Research Associates engage in fulltime laboratory research under the preceptorship of one of the senior staff. All associates may participate in tutorial seminars and other teaching programs.

Clinical Associates usually begin their appointments at the completion of residency training. Exceptionally well qualified individuals, however, can be appointed earlier in their training. The Clinical Center is approved for 1 year of psychiatric residency training at the PGY4 level. Since selections for these positions will be made in the spring of 1981, PGY2 or PGY3 psychiatric residents may now apply.



Applications are due by January 30, 1981 for appointments which begin July 1982. Both U.S. citizens and noncitizens can apply.

A competitive salary is available for candidates qualifying for appointment in the Commissioned Corps, United States Public Health Service. A portion of the salary is tax exempt. Moving and travel expenses are paid and health care is free. Appointment as a Staff Fellow or a Visiting Associate is also available.

For a detailed catalog about the program, write or call collect:

Helps weather
the manic storm

maintenance therapy with Eskalith®

brand of

lithium carbonate

300 mg capsules and
300 mg scored tablets

In manic-depressive patients with a history of mania, 'Eskalith'

- **prevents or diminishes the intensity of future episodes**
- **can increase the intervals between episodes**
- **helps patients function within normal limits**

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

> **WARNING**
> Lithium toxicity is closely related to serum lithium levels, and can occur at doses close to therapeutic levels. Facilities for prompt and accurate serum lithium determinations should be available before initiating therapy.

INDICATIONS: Treatment of manic episodes of manic-depressive illness. Maintenance therapy prevents or diminishes the intensity of subsequent episodes in manic-depressive patients with a history of mania.

WARNINGS: Lithium should generally not be given to patients with significant renal or cardiovascular disease, severe debilitation or dehydration, sodium depletion, or to patients receiving diuretics.

Lithium may prolong the effects of neuromuscular blocking agents. Such agents should be given with caution to patients receiving lithium. Lithium therapy has been reported in some cases to be associated with morphologic changes in the kidneys. The relationship between such changes and renal function has not been established.

Caution patient and family to watch for diarrhea, vomiting, tremor, mild ataxia, drowsiness, or muscular weakness as signs of lithium toxicity, and to discontinue therapy and contact a physician should they occur. Patients receiving combined therapy with lithium and an antipsychotic should be monitored closely for early evidence of neurologic toxicity and treatment discontinued promptly if such signs appear. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery).

Lithium should not be used in pregnancy, especially during the first trimester, unless potential benefits outweigh possible hazards. Except in rare and unusual circumstances, nursing should not be undertaken while a patient is on lithium therapy, since lithium is excreted in human milk.

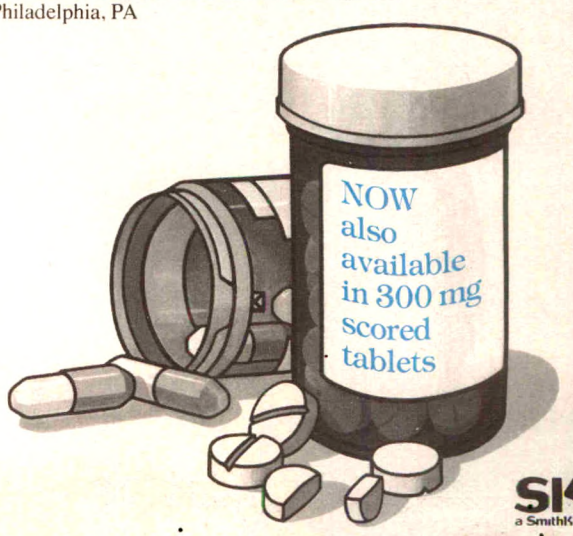
Not recommended for children under 12.

PRECAUTIONS: Lithium tolerance is greater during the acute manic phase and decreases when manic symptoms subside.

Lithium therapy may lead to sodium depletion. Normal diet (including salt) and adequate fluid intake (2500-3000 ml.) must be maintained, at least during initial stabilization period. Protracted sweating or diarrhea can decrease tolerance; in such cases, administer supplemental fluid and salt.

Sweating, diarrhea, and concomitant infection with elevated temperatures may require temporary reduction or cessation of dosage.

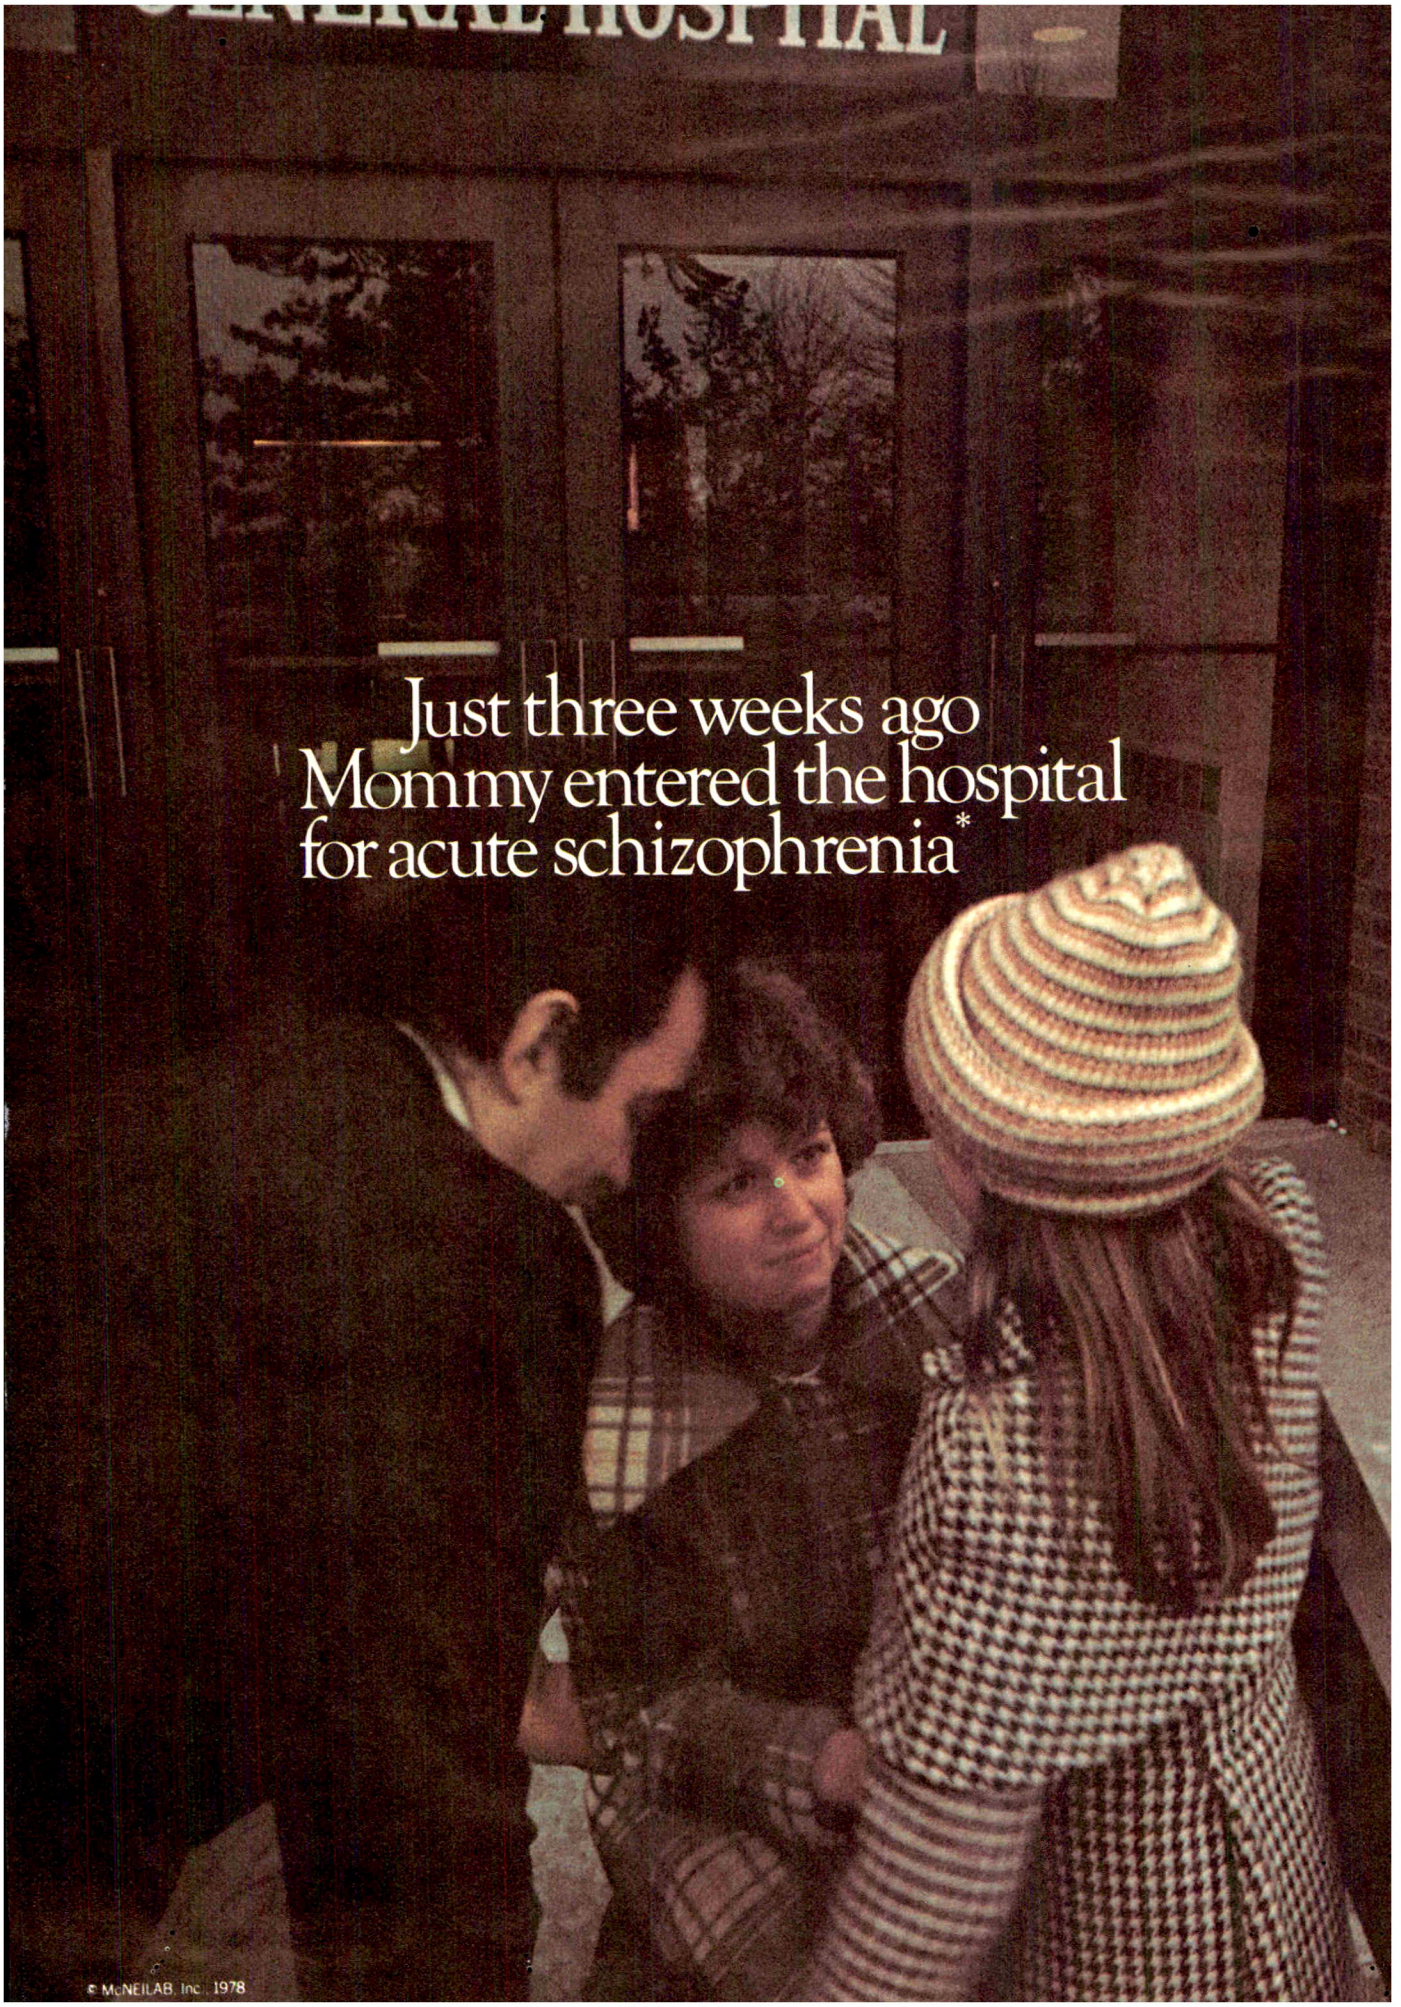
Where hypothyroidism exists, thyroid function should be monitored during lithium stabilization and maintenance; where hypothyroidism occurs during stabilization and maintenance, supplemental thyroid treatment may be used.



ADVERSE REACTIONS: Mild to moderate toxic reactions may occur at serum lithium levels from 1.5 to 2.5 mEq./1., and moderate to severe reactions at levels from 2.0 to 2.5 mEq./1. Fine hand tremor, polyuria, and mild thirst may occur during initial therapy and persist. Transient and mild nausea and general discomfort may also appear during initial therapy. These effects usually subside with continued treatment or temporary reduction or cessation of dosage. If persistent, discontinue dosage. Diarrhea, vomiting, drowsiness, muscular weakness, and lack of coordination may be early signs of toxicity and may occur at levels below 2.0 mEq./1. At higher levels, ataxia, giddiness, tinnitus, blurred vision, and a large output of dilute urine may be seen. Serum levels above 3.0 mEq./1. may produce a complex clinical picture, involving multiple organs and systems. Serum levels should not exceed 2.0 mEq./1. during acute phase.

The following reactions appear to be related to serum lithium levels, including levels within the therapeutic range: **Neuromuscular**—tremor, muscle hyperirritability (fasciculations, twitching, clonic movements of whole limbs), ataxia, choreo-athetotic movements, hyperactive deep tendon reflex; **Central Nervous System**—blackout spells, epileptiform seizures, slurred speech, dizziness, vertigo, incontinence of urine or feces, somnolence, psychomotor retardation, restlessness, confusion, stupor, coma; **Cardiovascular**—cardiac arrhythmia, hypotension, peripheral circulatory collapse; **Gastrointestinal**—anorexia, nausea, vomiting, diarrhea; **Genitourinary**—albuminuria, oliguria, polyuria, glycosuria; **Dermatologic**—drying and thinning of hair, alopecia, anesthesia of skin, chronic folliculitis, exacerbation of psoriasis, xerosis cutis; **Autonomic**—blurred vision, dry mouth; **Thyroid Abnormalities**—euthyroid goiter and/or hypothyroidism (including myxedema) with lower T_3 and T_4. I^{131} uptake may be elevated; rare cases of hyperthyroidism; **EEG Changes**—diffuse slowing, widening of the frequency spectrum, potentiation and disorganization of background rhythm; **EKG Changes**—reversible flattening, isoelectricity or inversion of T-waves; **Miscellaneous**—fatigue, lethargy, transient scotomata, dehydration, weight loss, tendency to sleep.

Reactions unrelated to dosage include: transient EEG and EKG changes, leukocytosis, headache, diffuse nontoxic goiter with or without hypothyroidism, transient hyperglycemia, generalized pruritus with or without rash, cutaneous ulcers, albuminuria, worsening of organic brain syndromes, excessive weight gain, edematous swelling of ankles or wrists, thirst or polyuria, sometimes resembling diabetes insipidus, and metallic taste. A single case of a syndrome resembling Raynaud's has been reported.



HOW SUPPLIED: 300 mg. capsules in bottles of 100.
300 mg. scored tablets in bottles of 100.

Haldol®
(haloperidol)
tablets/concentrate/injection

Promptly controls psychotic symptoms... usually leaving the patient more responsive to therapy

Rapid onset of therapeutic effect in a wide range of psychotic symptoms.[1-4]

Helps avoid long-term hospitalization.[1-3,5]

Minimal risk of hypotension, oversedation, or troublesome anticholinergic effects.[1,4,6,7,9-11]
Transient hypotension occurs rarely; severe orthostatic hypotension has not been reported. Although some instances of drowsiness have been reported, marked sedation is rare.

Permits aggressive titration to effective dosage levels for optimal control.[5,6]

Often leaves patient with improved insight,
with a renewed interest in the environment, and more likely to participate in therapeutic efforts.[1,7]

Common side effects easily controlled.[1,4-6,8,9]
Although extrapyramidal symptoms (EPS) have been reported frequently, they are usually dose-related and readily controlled with dose adjustment or antiparkinson drugs. EPS often diminish spontaneously with continued use of HALDOL haloperidol.

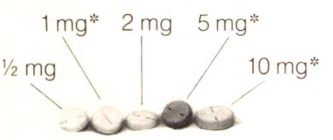
*Not an actual case history, this situation illustrates the action of HALDOL haloperidol as reported in various clinical studies (available on request).

Please turn page for summary of prescribing information.

concentrate

A tasteless, odorless, colorless Liquid Concentrate for better patient acceptability: 2 mg per ml haloperidol (as the lactate).



injection

A rapid-acting injection for psychiatric emergencies: 5 mg haloperidol (as the lactate) with 1.8 mg methylparaben and 0.2 mg propylparaben per ml, and lactic acid for pH adjustment to 3.4 ± 0.2.

tablets

5 tablet strengths for convenience in individualizing dosage:

HALDOL® (haloperidol)

*contain FD&C Yellow No. 5 (see Precautions).

tablets/concentrate/injection

A dosage form for every therapeutic need

Summary of Prescribing Information

Contraindications: Severe, toxic CNS depression or comatose states from any cause, hypersensitivity to the drug, Parkinson's disease.

Warnings: ***Usage in Pregnancy:*** Safe use in pregnancy or in women likely to become pregnant has not been established; use only if benefit clearly justifies potential hazards. Infants should not be nursed during drug treatment.

Combined Use With Lithium: Patients receiving lithium plus haloperidol should be monitored closely for early evidence of neurological toxicity.

General: Bronchopneumonia, sometimes fatal, has followed use of major tranquilizers, including haloperidol. Prompt remedial therapy should be instituted if dehydration, hemoconcentration or reduced pulmonary ventilation occurs, especially in the elderly. Decreased serum cholesterol and/or cutaneous and ocular changes have been reported with chemically-related drugs, although not with haloperidol. Mental and/or physical abilities required for hazardous tasks or driving may be impaired. Alcohol should be avoided due to possible additive effects and hypotension.

Precautions: Administer cautiously to patients: (1) with severe cardiovascular disorders, due to the possibility of transient hypotension and/or precipitation of anginal pain (if a vasopressor is required, epinephrine should not be used since HALDOL haloperidol may block its vasopressor activity and paradoxical further lowering of blood pressure may occur); (2) receiving anticonvulsant medication since HALDOL haloperidol may lower the convulsive threshold; (3) with known allergies or a history of allergic reactions to drugs; (4) receiving anticoagulants. Concomitant antiparkinson medication, if required, may have to be continued after HALDOL haloperidol is discontinued because of different excretion rates; if both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson drugs, are administered concomitantly with HALDOL haloperidol. When HALDOL haloperidol is used for mania in cyclic disorders, there may be a rapid mood swing to depression. Severe neurotoxicity may occur in patients with thyrotoxicosis receiving antipsychotic medication, including HALDOL haloperidol. FD&C Yellow No. 5 (tartrazine) may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, especially in those who have aspirin hypersensitivity.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions:* Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which were usually mild to moderately severe and usually reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally, extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Antiparkinson drugs may be required. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases.

Withdrawal Emergent Neurological Signs: Abrupt discontinuation of short term antipsychotic therapy is generally uneventful. However, some patients o maintenance treatment experience transient dyskinetic signs after abrup withdrawal. In certain cases these are indistinguishable from "Persistent Ta dive Dyskinesia" except for duration. It is unknown whether gradual with drawal will reduce the occurrence of these signs, but until further evidence available haloperidol should be gradually withdrawn.

Persistent Tardive Dyskinesia: Although rarely reported with HALDOL halo peridol, tardive dyskinesia may appear during or after long-term therapy. Th risk appears to be greater in elderly patients on high-dose therapy, especial females. Symptoms are persistent and sometimes appear irreversible; there no known effective treatment and all antipsychotic agents should be discon tinued. The syndrome may be masked by reinstitution of drug, increasin dosage, or switching to a different antipsychotic agent.

Other CNS Effects: Insomnia, restlessness, anxiety, euphoria, agitation drowsiness, depression, lethargy, headache, confusion, vertigo, grand m seizures, and exacerbation of psychotic symptoms.

Cardiovascular Effects: Tachycardia and hypotension. ***Hematologi Effects:*** Reports of mild, usually transient leukopenia and leukocytosis, min mal decreases in red blood cell counts, anemia, or a tendency toward lyn phomonocytosis; agranulocytosis rarely reported and only in association wit other medication. ***Liver Effects:*** Impaired liver function and/or jaundic reported. ***Dermatologic Reactions:*** Maculopapular and acneiform reaction isolated cases of photosensitivity, loss of hair. ***Endocrine Disorders:*** Lact tion, breast engorgement, mastalgia, menstrual irregularities, gynecomasti impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointe tinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspepsi nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, u nary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bro chospasm and increased depth of respiration.

The injectable form is intended only for acutely agitated psychotic patien with moderately severe to very severe symptoms.

Caution: Federal law prohibits dispensing without prescription. 08

IMPORTANT: Full directions for use should be read before HALDO haloperidol is administered or prescribed.

HALDOL tablets and concentrate (120 ml) are manufactured by McN Laboratories Co., Dorado, PR 00646. ©McN 198

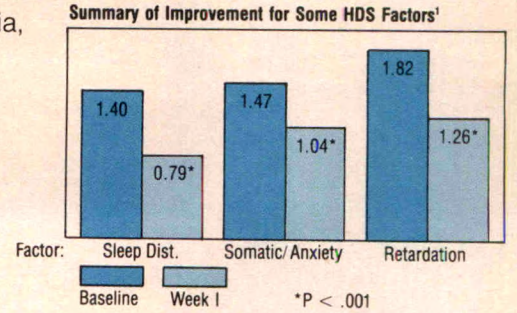
When depressive symptoms come in a cluster of blues...:



Adapin® (doxepin HCl) helps patients see life in all its colors

Improvements noted at one week

Depressed patients often present with fatigue, anorexia, anxiety, mood swings, loss of interest, *and most frequently, early awakening and insomnia*. In a summation of 9 clinical studies involving 198 patients, significant clinical improvement was noted after the first week of doxepin treatment.[1] However, optimal antidepressant response may not be evident for two to three weeks.

Summary of Improvement for Some HDS Factors[1]

Normalized sleep patterns

In a study of clinically depressed patients with symptoms of insomnia, treatment with doxepin significantly reduced difficulty falling asleep, difficulty staying asleep and frequency of early morning awakening.[2]

Low potential for cardiotoxicity

The incidence of tachycardia and hypotension, which have been observed during treatment with tricyclic antidepressants, has been reported infrequently with doxepin. In 452 patients given doxepin, the incidence of tachycardia was 2.88%; in 495 patients, the incidence of hypotension was 2.62%.[3]

Now available... 75 mg capsules for h.s. dosage

Brief Summary of Prescribing Information ADAPIN® (doxepin HCl) Capsules
Indications–Relief of symptoms of anxiety and depression.
Contraindications–Glaucoma, tendency toward urinary retention or hypersensitivity to doxepin.
Warnings–Adapin has not been evaluated for safety in pregnancy. No evidence of harm to the animal fetus has been shown in reproductive studies. There are no data concerning secretion in human milk, nor on effect in nursing infants.

Usage in children under 12 years of age is not recommended. MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug, as serious side-effects and death have been reported with the concomitant use of certain drugs and MAO inhibitors.

In patients who may use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions–Drowsiness may occur and patients should be cautioned against driving a motor vehicle or operating hazardous machinery. Since suicide is an inherent risk in depressed patients they should be closely supervised while receiving treatment. Although Adapin has shown effective tranquilizing activity, the possibility of activating or unmasking latent psychotic symptoms should be kept in mind. This product contains FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

Adverse Reactions–Dry mouth, blurred vision and constipation have been reported. Drowsiness has also been observed.

Adverse effects occurring infrequently include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as sweating, tachycardia and hypotension. Weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash and pruritus may also occur.

Dosage and Administration–In mild to moderate anxiety and/or depression: 25 mg t.i.d. Increase or decrease the dosage according to individual response. Daily dosage, up to 150 mg may be taken at bedtime without loss of effectiveness. Usual optimum daily dosage is 75 mg to 150 mg per day not to exceed 300 mg per day.

Antianxiety effect usually precedes the antidepressant effect by two or three weeks.

How Supplied–Each capsule contains doxepin, as the hydrochloride. 10 mg, 25 mg, 50 mg, 75 mg and 100 mg capsules in bottles of 100 and 1000.

For complete prescribing information please see package insert or PDR.

Adapin® (doxepin HCl) ... effective single-entity drug with antidepressant and antianxiety effects

A-252

CONVENIENCE, COMPLIANCE

One prescription to write, one prescription for the patient to have filled and usually only one tablet per dose to take. Two dosage strengths simplify titration.

Less trouble with treatment dropouts – early relief encourages patients to stay with their regimen. In a nationwide, multicenter study there were fewer dropouts due to side effects or treatment failure with Limbitrol than with amitriptyline alone.*

More than an antidepressant, without a phenothiazine – for *nonpsychotic* anxious depression. Limbitrol combines the antidepressant action of amitriptyline with the *specifically effective* antianxiety action of Librium® (chlordiazepoxide HCl/Roche), for efficacy while minimizing phenothiazine risks.†

Broad symptomatic relief – symptoms likely to respond in the first week of treatment include insomnia, agitation, psychic and somatic anxiety, anorexia and feelings of guilt or worthlessness.

*Data on file, Medical Department, Hoffmann-La Roche Inc.

†The causal relationship between the phenothiazines and extrapyramidal side effects, including tardive dyskinesia, is well established. In contrast the reported incidence of these adverse reactions with Limbitrol or either of its components is rare. (For a complete list of side effects reported with Limbitrol, consult full disclosure.)

ROCHE®

A CLEAR-CUT RATIONALE AND A COMFORTABLE PATIENT

Fundamental reasons to start prescribing

Limbitrol® IV

Tablets 5-12.5 each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)
Tablets 10-25 each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt)

for moderate depression and anxiety

Please see following page for a summary of product information.

LIMBITROL® TABLETS Tranquilizer-Antidepressant

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Relief of moderate to severe depression associated with moderate to severe anxiety.
Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants. Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.
Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.)
***Usage in Pregnancy:* Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**
Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage; withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline; symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).
Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (e.g., operating machinery, driving). Periodic liver function tests and blood counts are recommended during prolonged treatment. Amitriptyline component may block action of guanethidine or similar antihypertensives. Concomitant use with other psychotropic drugs has not been evaluated: sedative effects may be additive. Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12.
In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.
Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline. Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.
This list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs:
Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.
Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.
Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.
Anticholinergic: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urinary tract.
Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.
Hematologic: Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia.
Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.
Endocrine: Testicular swelling and gynecomastia in the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female and elevation and lowering of blood sugar levels.
Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaundice, alopecia, parotid swelling.
Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. I.V. administration of 1 to 3 mg physostigmine salicylate has been reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestation and treatment.
Dosage: Individualize according to symptom severity and patient response. Reduce to smallest effective dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at bedtime. Single h.s. dose may suffice for some patients. Lower dosages are recommended for the elderly.
Limbitrol 10-25, initial dosage of three to four tablets daily in divided doses, increased up to six tablets or decreased to two tablets daily as required. Limbitrol 5-12.5, initial dosage of three to four tablets daily in divided doses, for patients who do not tolerate higher doses.
How Supplied: White, film-coated tablets, each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt) and blue, film-coated tablets, each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt) — bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50.

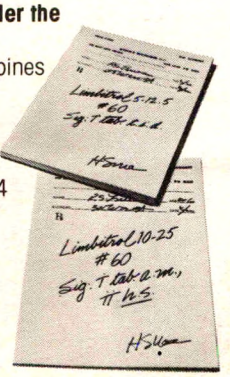
Your guide to patient management... when you decide medication is needed

How to initiate and maintain therapy

Select dosage strength appropriate for each patient
☐ Limbitrol 5-12.5 is recommended to minimize drowsiness and for elderly patients
☐ Limbitrol 10-25 may be indicated for patients who tolerate medication without undue side effects

Specify daily dosage based on symptom severity
☐ An initial dosage of three tablets is recommended
☐ Dosage may be increased to six tablets or decreased to two tablets daily as necessary
☐ Once a satisfactory response is obtained, patients should be continued on the smallest dose required to maintain remission



Utilize dosage options to best accommodate individual patient needs
☐ T.I.D. or Q.I.D., familiar regimens most suited for patients who tolerate medication without undue drowsiness
☐ Two tablets one hour before bedtime and one tablet midday may minimize daytime drowsiness and help relieve a common target symptom—insomnia
☐ Entire dosage h.s. to take maximum advantage of the sedative effect

How to make each patient an informed patient

1. Discuss with patients the probability that they will experience drowsiness, especially during the first week.
2. Reassure your patients that drowsiness is one indication that the medication is working and that it may help alleviate their insomnia.
3. Encourage patients to report if drowsiness becomes troublesome so that, if necessary, dosage schedule can be adjusted.
4. Caution patients about the combined effects with alcohol or other CNS depressants. Let them know that the additive effects may produce a harmful level of sedation and CNS depression.
5. Caution patients about activities requiring complete mental alertness, such as operating machinery or driving a car.
6. Warn pregnant patients and patients of childbearing age that the safety of Limbitrol in pregnancy has not yet been established.

Please see complete product disclosure for other pertinent information.

Limbitrol should not be used under the following circumstances:
1. Hypersensitivity to benzodiazepines or tricyclic antidepressants.
2. Concomitantly with an MAO inhibitor. To replace an MAO inhibitor with Limbitrol, discontinue MAO inhibitor for a minimum of 14 days before cautiously initiating Limbitrol therapy.
3. During the acute recovery phase following myocardial infarction.

In moderate depression and anxiety

Limbitrol®

Relief without a phenothiazine

CLORAZEPATE DIPOTASSIUM

Tranxene® CT

Ideal for short-term antianxiety therapy

Acts promptly...tapers gently at discontinuation

Tranxene goes to work in minutes

Nordiazepam uptake is rapid, with pharmacologic effects reported within 30 minutes.[1] Peak serum levels are attained within 1-2 hours after dosing.

Allows post-therapy adjustment time

When administration stops, nordiazepam serum levels taper at a gentle rate. This built-in taper may give your patients more time to adjust to cessation of therapy.[2]

1. Sedation reported in normal volunteers 30 minutes after dosing. Tranxene Drug Monograph 97-0185, p. 9, 1979.
2. The elimination kinetics of an agent can be closely defined, but these cannot at present be directly related to therapeutic or adverse effects.

Abbott Laboratories, North Chicago, IL 60064

0043331

Brief Summary

INDICATIONS — Symptomatic relief of anxiety and tension associated with anxiety disorders, other psychoneurotic disorders, transient situational disturbances, and functional or organic disorders. Symptomatic relief of acute alcohol withdrawal.

Effectiveness in long-term use (over 4 months) not assessed by systematic clinical studies. Physician should periodically reassess usefulness for each patient.

CONTRAINDICATIONS — Known hypersensitivity to the drug. Acute narrow angle glaucoma.

WARNINGS — Not for use in depressive neuroses or psychotic reactions. Caution patients against hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles. Advise against simultaneous use of other CNS depressants, and caution patients that effects of alcohol may be increased. Not recommended for patients under 18. Nervousness, insomnia, irritability, diarrhea, muscle aches, and memory impairment have followed abrupt withdrawal from long-term high dosage. Withdrawal symptoms were reported after abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months. Use caution in patients having psychological potential for drug dependence (dependence has been observed in dogs and rabbits).

Pregnancy and Lactation: Minor tranquilizers should almost always be avoided first trimester. Consider possibility of pregnancy before initiating therapy. Patient should consult physician about discontinuation if she becomes pregnant or plans pregnancy. Do not give to nursing mothers.

PRECAUTIONS — Observe usual precautions in depression accompanying anxiety, or in patients with suicidal tendency, or those with impaired renal or hepatic function. Do periodic blood counts and liver function tests during prolonged therapy. Use small doses and gradual increments in the elderly or debilitated.

ADVERSE REACTIONS — Drowsiness, dizziness, various g.i. complaints, nervousness, blurred vision, dry mouth, headache, mental confusion, insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression, slurred speech, abnormal liver and kidney function, decreased hematocrit, decreased systolic blood pressure.

DOSAGE — ANXIETY—Usual daily dose 30 mg or less (start the elderly or debilitated at 7.5-15 mg). Adjust gradually within 15-60 mg daily range. Capsules and scored tablets: divided doses; or once daily h.s. (start patient at 15 mg). Single Dose Tablets, 22.5 mg (for patients stabilized on 7.5 mg t.i.d.) or 11.25 mg: once daily at any hour. ALCOHOL WITHDRAWAL—In divided doses: 1st day 30 mg initially, then 30-60 mg; 2nd day 45-90 mg; 3rd day 22.5-45 mg; 4th day 15-30 mg. Then taper to 15-7.5 mg daily, and discontinue as soon as stable.

INTERACTIONS — Potentiation may occur with ethyl alcohol, hypnotics, barbiturates, narcotics, phenothiazines, MAO inhibitors, other antidepressants.

OVERDOSAGE — Take general measures as for any CNS depressant.

SUPPLIED — Tranxene (clorazepate dipotassium) 3.75, 7.5, and 15 mg capsules and scored tablets. Tranxene-SD Half Strength 11.25 and Tranxene-SD 22.5 mg single dose tablets.

Acts promptly*...tapers gently at discontinuation

NDIFFERENCE

'STELAZINE' HELPS FIND A WAY THROUGH

The schizophrenic patient is often withdrawn, aloof and emotionally unresponsive. For such patients, 'Stelazine' provides effective, unsurpassed control of these and other psychotic symptoms.

Also important, 'Stelazine' can help patients participate in your therapeutic programs. 'Stelazine' usually does not cause excessive sedation and offers the convenience of b.i.d. dosage.

In fact, no other antipsychotic agent has demonstrated significantly greater overall effectiveness and significantly fewer adverse effects than 'Stelazine'.

'Stelazine'. A first choice for therapy.

Before prescribing, see complete prescribing information in SK&F Co. literature or PDR. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Generally avoid using in patients hypersensitive (e.g., blood dyscrasias, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Additive effect is possible with other C.N.S. depressants, including alcohol.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Patients with a history of long-term therapy with 'Stelazine' and/or other neuroleptics should be evaluated periodically for possible adjustment or discontinuance of drug therapy.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudo-parkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions, peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only), 10 mg./ml.

UNIVERSITY LIBRARY

Continuous Offering: PKSAP IV

- NO REGISTRATION DEADLINES
- FLEXIBLE PARTICIPATION TIME
- CENTRAL SCORING SERVICES AVAILABLE (See Schedule Below)
- CME CATEGORY I APPLICABLE (if MCQ is centrally scored)

PSYCHIATRIC KNOWLEDGE AND SKILL SELF-ASSESSMENT PROGRAM

The Program

The PKSAP provides a comprehensive approach to self-study that focuses on recent advances in psychiatry. PKSAP-IV is completely revised and represents a considerable expansion over previous editions. The program includes 180 multiple-choice questions (MCQs) and 7 patient management problems (PMPs). For the first time, participants will receive a comprehensive syllabus of current knowledge in psychiatry to use in studying for the program as well as a critique book that explains the rationale for the answers. References will be provided for program follow-up.

Continuing Medical Education Credit

If a subscriber completes and returns the MCQ answer sheet for central scoring prior to the designated deadline, a maximum of forty (40) credit hours may be claimed in Category I. For those completing the program BUT do not return the MCQ answer sheets for scoring, hour-for-hour credit may be claimed in Category 5A, up to twenty-two (22) hour limit.

PERIODIC SCORING & REPORTING SCHEDULE:

If MCQ Answer Sheet Received By:	Performance Report Returned By:

Information for Contributors

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material, have not been published previously, are not being considered for publication elsewhere, and have been approved by each author.

Copyright

The *Journal* requires express transfer of copyright to the American Psychiatric Association so that the author(s) and the Association are protected from misuse of copyrighted material. Authors of accepted papers will be asked to sign the following statement:

In consideration of the *American Journal of Psychiatry*'s taking action in reviewing and editing my submission [include title here] the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the American Psychiatric Association in the event that such work is published by the American Psychiatric Association.

Work done as part of an individual's duties as a federal employee is in the public domain. In such cases the following wording should be used:

The work described in [include title here] was done as part of my (our) employment with the federal government and is therefore in the public domain.

In addition, authors must obtain letters of permission from publishers for use of extensive quotations (more than 500 words) and of tables and figures that originally appeared elsewhere.

Patient Anonymity

Ethical as well as legal considerations require careful attention to the protection of a patient's anonymity in case reports and elsewhere. Identifying information such as names, initials, hospital numbers, and dates must be avoided. In addition, authors should disguise identifying information about a patient's characteristics and personal history.

Informed Consent

Manuscripts that report the results of experimental investigation with human subjects must include a statement that informed consent was obtained after the procedure(s) had been fully explained.

Review Process

Papers are reviewed by at least two experts to determine the originality, validity, and significance of content and conclusions. Authors will usually be advised within 3–4 months of the decision on their paper, although delays are sometimes unavoidable. Reviewers' comments will be returned with rejected manuscripts if they are judged to be useful to the authors. All reviewers remain anonymous.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to John C. Nemiah, M.D., Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. All correspondence will be sent to the first-named author unless otherwise specified. Papers that are not accompanied by a cover letter indicating that the paper is intended for publication will not be reviewed until such a statement is received. On a separate sheet include the names and mailing addresses of any authors who are not members of APA; they will be sent a complimentary copy of the issue in which their article appears.

Authors will be notified as soon as possible of the receipt of their paper and the number assigned to it. **This number must be included in all further correspondence.** It is imperative that the corresponding author of submitted papers notify the *Journal* of changes of address.

Annual Meeting Papers

The *Journal* has first refusal rights for numbered papers accepted for presentation at the Association's annual meetings, although not all papers can be published in the *Journal*. Authors of annual meeting papers should follow instructions they will receive in a letter from the Editor before the meeting. Annual meeting papers may be submitted for review before the meeting only if they are in **final form,** i.e., are ready for review. Authors must **not** submit their papers before the meeting if they expect any substantive revisions due to discussion at the meeting, further research, etc. These papers are subject to the same peer review criteria as other submissions. Authors who wish to submit their papers elsewhere must secure permission from the Editor. The *Journal* will assign its own number to each paper received for review; **this number must appear in any further communications about the paper.**

Length

The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles—3,800 words or the equivalent **(no more than 15 double-spaced pages, including references, tables, and figures).** Brief Communications—2,500 words **(no more than 10 double-spaced pages, including references, tables, and figures).** Clinical and Research Reports—1,000 words, 10 references, 1 table (no figures are used). Letters to the Editor—500 words, 5 references. The number of words, tables, and figures should be noted on the title page.

TYPES OF ARTICLES

Overviews

Overview articles attempt to bring together important relevant information on a topic of general interest to psychiatry. They are usually written at the invitation of the Editor; authors who have ideas for overview articles are advised to check with the Editor to ensure that a similar work is not in preparation. Overviews should not exceed 7,500 words **(no more than 25 double-spaced pages—including tables and figures—and 100 references).** All overviews, including those written by invitation, are given the same peer review received by other papers.

Regular Articles and Brief Communications

The primary difference between these two types of papers is length. The "brief communication" designation does not imply less sophisticated or complete work: it merely means that the content can be expressed within the upper limit of 2,500 words. There is no difference in the review procedure or scheduling of these articles. Authors who submit unnecessarily long articles with redundancies and loose writing style will be asked to shorten them, which can delay publication. Authors should choose their words carefully, avoiding lengthy introductions containing material that is common knowledge, summaries that merely repeat the results, unnecessary tables, figures, or references, etc. Single case reports should be submitted as Clinical and Research Reports.

Clinical and Research Reports

This section contains very brief articles (maximum of 1,000 words, 10 references, 1 table, and **no figures**) reporting new research findings, including preliminary data from pilot studies, and case reports that 1) describe new syndromes, 2) cast a new light on established ones, 3) indicate a new therapeutic procedure of potential value, or 4) describe adverse effects or previously unreported complications of drugs or therapeutic interventions. Because of the stringent criteria for this section, authors can expect more rapid publication than is possible in other sections. Submitted papers that substantially exceed the stated maximum length or contain figures will be returned to the author unreviewed.

Prompt Publication Policy

Articles submitted for prompt publication can be of either regular of Brief Communication length. (A "prompt publication policy" is automatically in effect for Clinical and Research Reports.) These papers are given priority in scheduling; however, authors should be aware that the minimum publication time is four months. Prompt publication papers must meet stringent criteria of originality and be of major immediate importance to the field. Authors must state their reasons for wanting rapid review in a cover letter to the Editor. It is important to think carefully about the nature of the paper before requesting prompt publication; a paper may be delayed if it is submitted inappropriately.

Other Sections

Letters to the Editor. Brief letters (maximum of 500 words and 5 references) will be considered if they include the notation "for publication" in the upper right corner. Letters critical of an article published in the *Journal* will automatically be sent to the authors for reply. Because of space limitations not all letters can be printed. The *Journal* is unable to notify authors of receipt of letters or to return those not published. All letters are subject to editing. Letters must be typed **double-spaced** throughout on letter-size bond paper; two copies are required. Letters that are not typed appropriately or do not conform to *Journal* reference style will be returned to the author for revision.

Book Reviews. Books for review may be sent directly to the Book Review Editor, Nancy C. Andreasen, M.D., University of Iowa College of Medicine, 500 Newton Rd., Iowa City, Iowa 52240. Book reviews are usually solicited by the Book Review Editor. Authors interested in reviewing a particular book are urged to contact the editorial office to see if the Book Review Editor wishes the book to be reviewed and to ascertain whether it has been previously assigned to another reviewer.

TYPING AND ARRANGING THE PAPER

All parts of the manuscript, including case reports, quotations, references, and tables, must be **double-spaced** throughout. All manuscripts must be typed in upper- and lowercase on one side only of 22 × 28 cm (8½ × 11 inches) **nonerasable** bond paper. All 4 margins must be 3¾ cm (1½ inches). The manuscript should be arranged in the following order, with each numbered item beginning a new page: 1) title page, 2) précis, 3) text, 4) references, 5) tables, 6) footnotes to text, and 7) figure captions. All pages must be numbered, with the title page as number 1. Please consult the following section on *Journal* style specifications for criteria for each part of the paper.

STYLE SPECIFICATIONS

Title Page

Title. The title should be informative but as brief as possible. Headline style (declarative sentences) should be avoided. Abbreviations and acronyms are rarely used in titles.

By-line. Authors named in the by-line should be limited to principal researchers and/or writers; collaborators can be acknowledged in a footnote. Degrees (other than honorary or undergraduate degrees) should be included after the authors' names.

Previous presentation. If the paper has been presented orally, please give the name of the meeting, the place, and inclusive dates.

Author affiliations. Provide the department, institution, city, and state where the work was done. If multiple locations and authors were involved, indicate in parentheses which authors were affiliated with each institution. Provide a full address for the author who is to receive reprint requests.

Acknowledgments. Acknowledgments should be in a separate paragraph on the title page. Grant support should include the full name of the granting agency as well as the grant number. Individual acknowledgments should be as brief as possible. Acknowledgments of companies that supplied drugs are used only in the case of experimental drugs or those unavailable in this country.

Other requirements. The number of words, tables, and figures should appear in the upper right corner and a phone number for the corresponding author in the lower right.

Précis

The précis should be up to 100 words for regular articles and Brief Communications. (No précis is used in the Clinical and Research Reports section.) The précis should be a single paragraph using complete, connected sentences, active verbs, and the third person. In most cases, the précis replaces a summary.

Text

Headings and subheadings should be inserted at reasonable intervals in all types of papers. Footnotes to text material should be typed on a separate page at the end of the manuscript. Summaries are rarely desirable, although a final "Comment" or "Conclusions" section may be used. The body of the paper should be written in the active voice and first person where appropriate.

Statistics. Authors should be sure that statistics used are

both necessary and appropriate. Statistical tests should be described and a reference citation given if the tests are not generally known. It is not sufficient to say "differences between the groups were significant." In cases of lengthy complicated analyses, the authors may summarize results and indicate that details are available from them on request.

Abbreviations. All abbreviations (other than those for metric units) should be explained the first time they are used. Idiosyncratic abbreviations should be avoided: overuse of abbreviations may hinder rather than facilitate readability.

Drugs. Generic rather than trade names of drugs should be used; trade names may be given parenthetically if necessary.

Units of measurement. All measurements should be in metric units; standard abbreviations are used.

References

References should be restricted to closely pertinent material: a complete review of the literature is rarely desirable. **Accuracy of citation is the author's responsibility.** References should conform exactly to the original spelling, accents, punctuation, etc. Authors should be sure that all references listed have been cited in text; no bibliographies can be used.

References are numbered and listed by their order of appearance in text; the text citation is followed by the appropriate reference number in parentheses. Do **not** arrange the list alphabetically.

Personal communications, unpublished manuscripts, manuscripts submitted but not yet accepted, and similar unpublished items should not appear in the reference list. Such citations may be noted in text or in a footnote. It is the author's responsibility to obtain permission to refer to another individual's unpublished observations. Manuscripts that are actually "in press" may be cited as such in the reference list; the name of the journal must be included.

Type references in the style shown below, **double-spaced throughout** (not just a line between references). List up to three authors; designate one or more authors past the third "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*; journals not indexed there should not be abbreviated.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349–365, 1967
3. Jones AB: Long-term administration of tricyclic antidepressants: three-year follow-up. Am J Psychiatry (in press)
4. Smythe JCW (ed): Psychiatry and Human Values. Springfield, Ill, Charles C Thomas, 1971
5. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968

Tables

Tables should be self-explanatory and should supplement rather than duplicate text. Authors may be asked to delete tables that present data which could be given succinctly in text or repeat information in the Results section. Tables are generally reserved for data presentation and not used as lists or charts. They should be **double-spaced** and no wider than 120 typewriter characters, including spaces. Consult recent issues of the *Journal* for table style. Please note that no vertical rules or internal horizontal rules are used. It is usually desirable to give both numbers and percentages where applicable. All units of measurement must be specified within the table. Metric measurements are used in tables and throughout the text. Each table should be identified numerically and include a concise but descriptive title. **A copy of each table should be included in each copy of the manuscript.**

Figures

Figures should be used only for data that cannot be adequately presented in text or tabular form. Figures should be submitted as glossy prints **with one photocopy attached to each manuscript copy.** The author's name and the title of the paper should appear on a gummed label affixed to the back of each glossy. All figures should be able to withstand reduction to about 8 cm (3¼ inches). Authors are urged to consider carefully the necessity of figures; they may be asked to delete figures that repeat information availabile in text. It is often advisable to obtain professional assistance in the preparation of figures.

PROCESSING OF ACCEPTED MANUSCRIPTS

Authors will be notified of acceptance of their papers; papers will then be edited and sent to the first-named (or corresponding) author for corrections and answers to editorial queries. No galley proofs are sent to authors, so the edited manuscript should be read with extreme care. Prompt return of edited manuscripts is essential. Authors who expect to be away from their offices for a long period or who change address after notification of acceptance should so inform the *Journal* office.

Manuscripts are accepted with the understanding that the Editor has the right to make revisions aimed at greater conciseness, clarity, and conformity with *Journal* style.

PERMISSION TO REPRINT

Written permission to reprint material published in the *Journal* must be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for such permission, except in cases of nonprofit classroom or library reserve use by instructors and educational institutions, or of authors who wish to reprint their own material. Requests will be facilitated if they are accompanied by written permission from the author of the material.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article.

THE AMERICAN PSYCHIATRIC ASSOCIATION
1700 Eighteenth Street, N.W., Washington, D.C. 20009

OFFICERS 1980–1981

President: DONALD G. LANGSLEY
President-Elect: DANIEL X. FREEDMAN
Vice-President: PETER A. MARTIN
Vice-President: ROBERT J. CAMPBELL
Secretary: H. KEITH H. BRODIE
Treasurer: GEORGE H. POLLOCK

ASSEMBLY

Speaker: MELVIN M. LIPSETT
Speaker-Elect: LAWRENCE HARTMANN
Recorder: HOWARD GUREVITZ

MEDICAL DIRECTOR'S OFFICE

Medical Director: MELVIN SABSHIN
Deputy Medical Directors: DONALD W. HAMMERSLEY
CAROLYN B. ROBINOWITZ
JEANNE SPURLOCK

  By George E. Vaillant et al

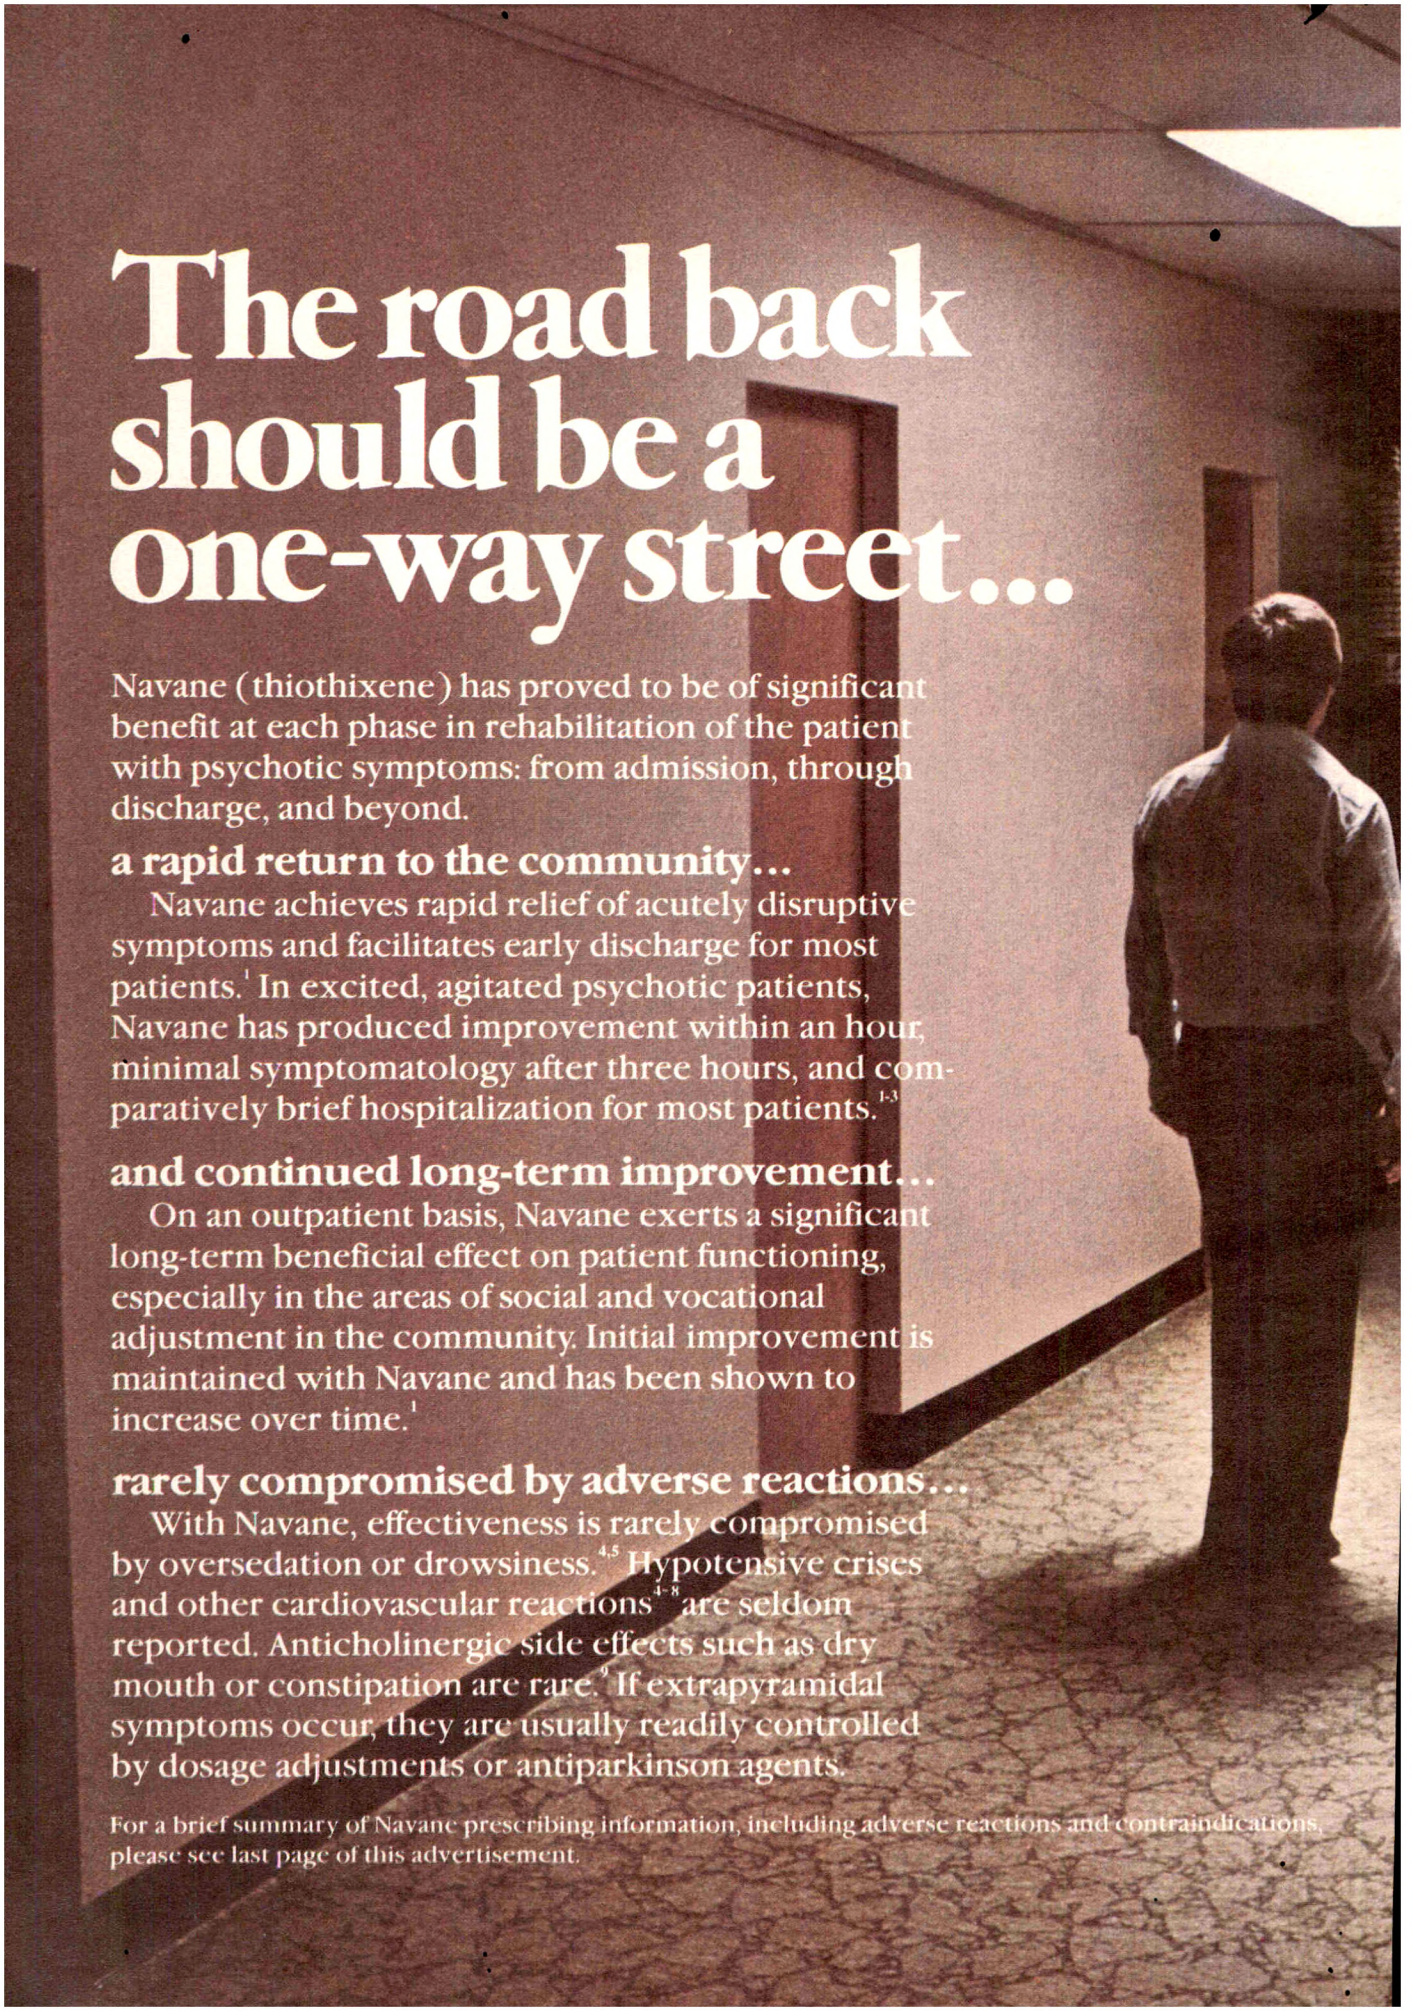
"Being entirely honest with oneself is a good exercise."

–SIGMUND FREUD

Sigmund Freud's legacy is central to our understanding of ourselves. Listen carefully, as radio draws you into the innermost thoughts and feelings of the 20th century's most influential people: Sigmund Freud, Simone de Beauvoir, Bertolt Brecht, Noam Chomsky, W.E.B. DuBois, William Faulkner, Michel Foucault, Robert Frost, James Joyce, Claude Lévi-Strauss, Bertrand Russell and Igor Stravinsky. Their lives and works are interpreted by some of the greatest performers of our day in a new series of audio essays from National Public Radio.

A Question of Place

Sound Portraits of 20th Century Humanists



Premieres Oct. 2*

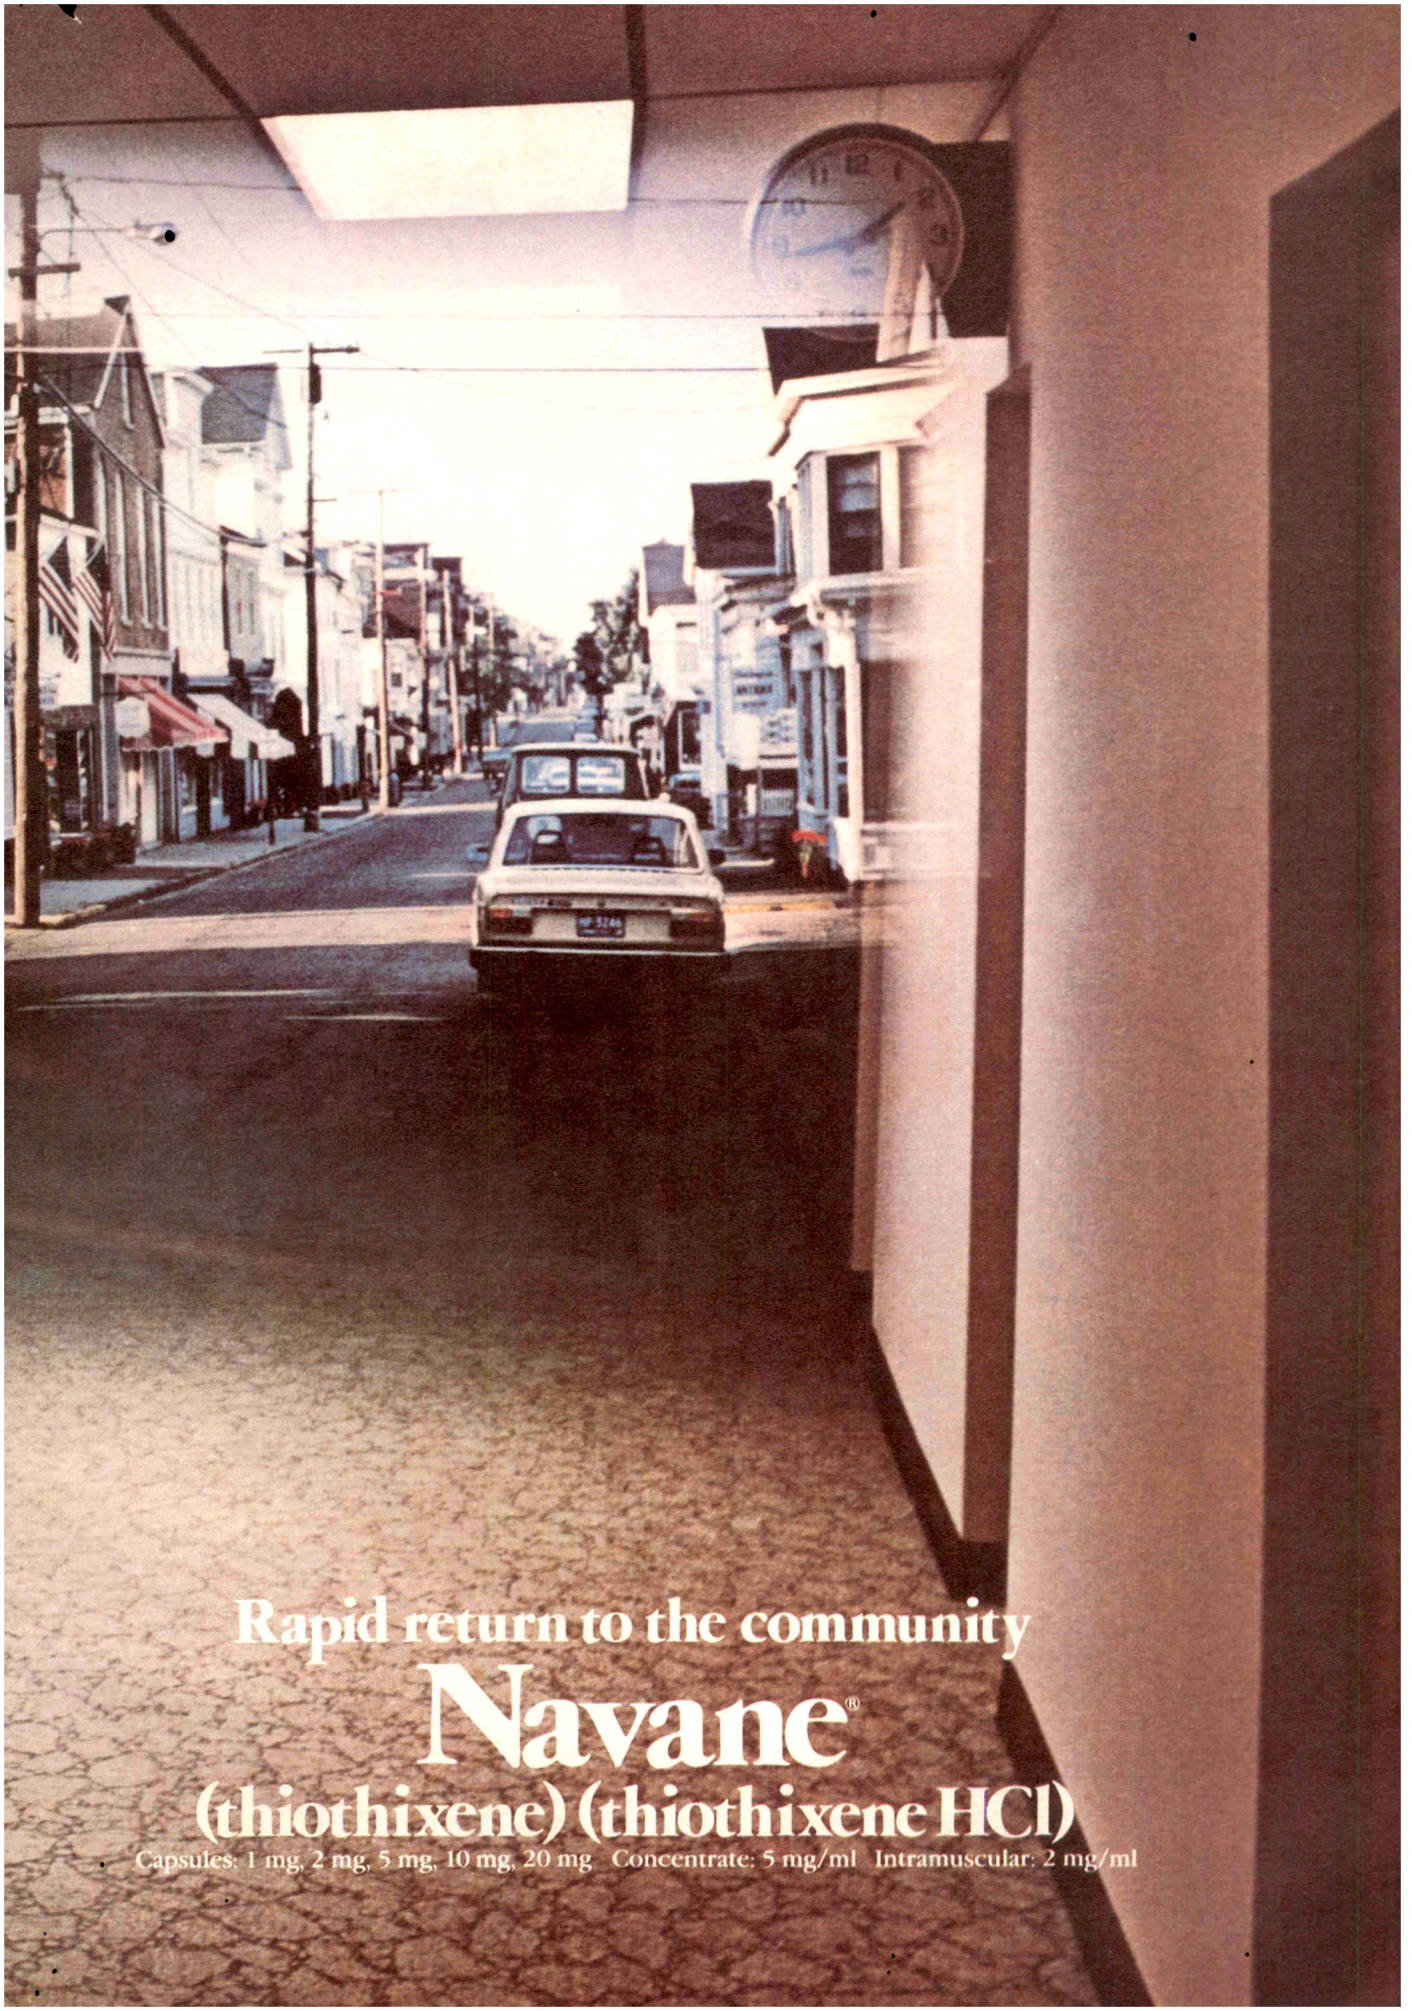
Series made possible by a grant from the National Endowment for the Humanities with additional funds from the Corporation for Public Broadcasting.

The road back should be a one-way street...

Navane (thiothixene) has proved to be of significant benefit at each phase in rehabilitation of the patient with psychotic symptoms: from admission, through discharge, and beyond.

a rapid return to the community...

Navane achieves rapid relief of acutely disruptive symptoms and facilitates early discharge for most patients.[1] In excited, agitated psychotic patients, Navane has produced improvement within an hour, minimal symptomatology after three hours, and comparatively brief hospitalization for most patients.[1-3]



and continued long-term improvement...

On an outpatient basis, Navane exerts a significant long-term beneficial effect on patient functioning, especially in the areas of social and vocational adjustment in the community. Initial improvement is maintained with Navane and has been shown to increase over time.[1]

rarely compromised by adverse reactions...

With Navane, effectiveness is rarely compromised by oversedation or drowsiness.[4,5] Hypotensive crises and other cardiovascular reactions[4-8] are seldom reported. Anticholinergic side effects such as dry mouth or constipation are rare.[9] If extrapyramidal symptoms occur, they are usually readily controlled by dosage adjustments or antiparkinson agents.

For a brief summary of Navane prescribing information, including adverse reactions and contraindications, please see last page of this advertisement.

Rapid return to the community

Navane®

(thiothixene) (thiothixene HCl)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

Rapid return to the community

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

BRIEF SUMMARY OF PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Contraindications. Navane (thiothixene) is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy*– Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration of Navane to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children– The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration– As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane (thiothixene). Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudo-parkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leukocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution – For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane (thiothixene) Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate– In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Stimulants that may cause convulsions (e.g. picrotoxin or pentylenetetrazol) should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg of thiothixene in bottles of 100, 1,000, and unit-dose pack of 100 (10 x 10's). Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100, 500, and unit-dose pack of 100 (10 x 10's).

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg, and in 30 ml (1 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, and 5 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10 vials. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

Everyone Knows He's a Pillar of Strength in the Community.

You Know He's an Alcoholic.

You've seen what stress can do to people: everything from ulcers and high blood pressure, to a sense of isolation or a broken family.

You've also witnessed another consequence of stress: dependence on alcohol or drugs.

If some of your patients have drinking or drug problems, you should know about Fenwick Hall, a unique treatment facility near Charleston, S.C.

Fenwick Hall was established by Dr. Morris Chafetz, founding director of the National Institute on Alcoholism and Alcohol Abuse and a leading authority on alcohol and drug dependence.

Fenwick Hall's carefully designed, highly individualized treatment is based on the needs Dr. Chafetz perceived during his 25 years of experience with both patients and programs.

Rather than treating only symptoms, Fenwick Hall's approach focuses on every facet of the individual. In addition to complete detoxification capabilities and highly qualified professionals delivering a superior program of therapy, counseling and education, Fenwick Hall provides recreational options such as tennis courts, a sauna and whirlpool bath and an indoor swimming pool.

Occupying a recently restored 18th-century estate, Fenwick Hall offers unusually elegant accommodations and a tranquility conducive to the growth of self-awareness and the restoration of well-being.

When individuals leave Fenwick Hall, they are able to return to their careers and homes, fortified with healthier ways of coping with the stress and struggles of daily life.

For further information, please write for our color brochure, or call John Magill, Executive Director.

MENTAL HEALTH AND INDUSTRY

Planning for the 80's

Volume VI, Problems of Industrial Psychiatric Medicine Series
Series Editor: Sherman N. Kieffer, M.D.

Based on a national conference devoted to psychiatric problems in industry, this volume explores the forthcoming challenges of industrial mental health in the 1980's. A synthesis of viewpoints is provided by leading authorities in the fields of mental health, medicine, labor and management. New psychological and medical problems that might emerge are considered, while the role of psychiatrists and community mental health professionals to meet these increasing demands is examined.

THE CHRONIC MENTALLY ILL

Treatment, Programs, Systems

Compiled by leading authorities in the field of mental health, this book offers a broad spectrum of care and treatment modalities for the chronic mentally ill. The most significant forms of treatment are described, including psychopharmacological therapy, medication monitoring, psychotherapy, socialization, housing, case management and vocational rehabilitation.

1980/Dec. **0-87705-086-4** **$29.95**

Chen, Ronald, M.D., F.A.C.P., F.A.P.A.

FOREIGN MEDICAL GRADUATES IN PSYCHIATRY

Issues and Problems

In the first major work of its kind, the author examines the personal and professional issues and problems of foreign medical graduates in America. Based on a three-year study, the book explores the response of psychiatric facilities that employ foreign physicians, and the attitudes of the general medical community to these professionals. Dr. Chen highlights the experiences of sixty-four foreign psychiatrists in seven training centers in the United States and Canada, and documents the reactions of 169 psychiatric facilities across the country.

CONVENIENCE, COMPLIANCE

One prescription to write, one prescription for the patient to have filled and usually only one tablet per dose to take. Two dosage strengths simplify titration.

Less trouble with treatment dropouts — early relief encourages patients to stay with their regimen. In a nationwide, multicenter study there were fewer dropouts due to side effects or treatment failure with Limbitrol.than with amitriptyline alone.*

More than an antidepressant, without a phenothiazine — for *nonpsychotic* anxious depression. Limbitrol combines the antidepressant action of amitriptyline with the *specifically effective* antianxiety action of Librium® (chlordiazepoxide HCl/Roche), for efficacy while minimizing phenothiazine risks.†

Broad symptomatic relief — symptoms likely to respond in the first week of treatment include insomnia, agitation, psychic and somatic anxiety, anorexia and feelings of guilt or worthlessness.

*Data on file, Medical Department, Hoffmann-La Roche Inc.

†The causal relationship between the phenothiazines and extrapyramidal side effects, including tardive dyskinesia, is well established. In contrast the reported incidence of these adverse reactions with Limbitrol or either of its components is rare. (For a complete list of side effects reported with Limbitrol, consult full disclosure.)

ROCHE®

A CLEAR-CUT RATIONALE AND A COMFORTABLE PATIENT

Fundamental reasons to start prescribing

Limbitrol® IV

Tablets 5-12.5 each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)
Tablets 10-25 each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt)

for moderate depression and anxiety

Please see following page for a summary of product information.

LIMBITROL® TABLETS Tranquilizer-Antidepressant

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Relief of moderate to severe depression associated with moderate to severe anxiety.
Contraindications: Known hypersensitivity to benzodiazepines or tricyclic antidepressants. Do not use with monoamine oxidase (MAO) inhibitors or within 14 days following discontinuation of MAO inhibitors since hyperpyretic crises, severe convulsions and deaths have occurred with concomitant use; then initiate cautiously, gradually increasing dosage until optimal response is achieved. Contraindicated during acute recovery phase following myocardial infarction.
Warnings: Use with great care in patients with history of urinary retention or angle-closure glaucoma. Severe constipation may occur in patients taking tricyclic antidepressants and anticholinergic-type drugs. Closely supervise cardiovascular patients. (Arrhythmias, sinus tachycardia and prolongation of conduction time reported with use of tricyclic antidepressants, especially high doses. Myocardial infarction and stroke reported with use of this class of drugs.)

***Usage in Pregnancy:* Use of minor tranquilizers during the first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Since physical and psychological dependence to chlordiazepoxide have been reported rarely, use caution in administering Limbitrol to addiction-prone individuals or those who might increase dosage; withdrawal symptoms following discontinuation of either component alone have been reported (nausea, headache and malaise for amitriptyline; symptoms [including convulsions] similar to those of barbiturate withdrawal for chlordiazepoxide).
Precautions: Use with caution in patients with a history of seizures, in hyperthyroid patients or those on thyroid medication, and in patients with impaired renal or hepatic function. Because of the possibility of suicide in depressed patients, do not permit easy access to large quantities in these patients. Caution patients about possible combined effects with alcohol and other CNS depressants and against hazardous occupations requiring complete mental alertness (e.g., operating machinery, driving). Periodic liver function tests and blood counts are recommended during prolonged treatment. Amitriptyline component may block action of guanethidine or similar antihypertensives. Concomitant use with other psychotropic drugs has not been evaluated: sedative effects may be additive. Discontinue several days before surgery. Limit concomitant administration of ECT to essential treatment. See Warnings for precautions about pregnancy. Limbitrol should not be taken during the nursing period. Not recommended in children under 12.
In the elderly and debilitated, limit to smallest effective dosage to preclude ataxia, oversedation, confusion or anticholinergic effects.
Adverse Reactions: Most frequently reported are those associated with either component alone: drowsiness, dry mouth, constipation, blurred vision, dizziness and bloating. Less frequently occurring reactions include vivid dreams, impotence, tremor, confusion and nasal congestion. Many depressive symptoms including anorexia, fatigue, weakness, restlessness and lethargy have been reported as side effects of both Limbitrol and amitriptyline. Granulocytopenia, jaundice and hepatic dysfunction have been observed rarely.
This list includes adverse reactions not reported with Limbitrol but requiring consideration because they have been reported with one or both components or closely related drugs:
Cardiovascular: Hypotension, hypertension, tachycardia, palpitations, myocardial infarction, arrhythmias, heart block, stroke.
Psychiatric: Euphoria, apprehension, poor concentration, delusions, hallucinations, hypomania and increased or decreased libido.
Neurologic: Incoordination, ataxia, numbness, tingling and paresthesias of the extremities, extrapyramidal symptoms, syncope, changes in EEG patterns.
Anticholinergic: Disturbance of accommodation, paralytic ileus, urinary retention, dilatation of urinary tract.
Allergic: Skin rash, urticaria, photosensitization, edema of face and tongue, pruritus.
Hematologic: Bone marrow depression including agranulocytosis, eosinophilia, purpura, thrombocytopenia.
Gastrointestinal: Nausea, epigastric distress, vomiting, anorexia, stomatitis, peculiar taste, diarrhea, black tongue.
Endocrine: Testicular swelling and gynecomastia in the male, breast enlargement, galactorrhea and minor menstrual irregularities in the female and elevation and lowering of blood sugar levels.
Other: Headache, weight gain or loss, increased perspiration, urinary frequency, mydriasis, jaundice, alopecia, parotid swelling.
Overdosage: Immediately hospitalize patient suspected of having taken an overdose. Treatment is symptomatic and supportive. I.V. administration of 1 to 3 mg physostigmine salicylate has been reported to reverse the symptoms of amitriptyline poisoning. See complete product information for manifestation and treatment.
Dosage: Individualize according to symptom severity and patient response. Reduce to smallest effective dosage when satisfactory response is obtained. Larger portion of daily dose may be taken at bedtime. Single h.s. dose may suffice for some patients. Lower dosages are recommended for the elderly.
Limbitrol 10-25, initial dosage of three to four tablets daily in divided doses, increased up to six tablets or decreased to two tablets daily as required. Limbitrol 5-12.5, initial dosage of three to four tablets daily in divided doses, for patients who do not tolerate higher doses.
How Supplied: White, film-coated tablets, each containing 10 mg chlordiazepoxide and 25 mg amitriptyline (as the hydrochloride salt) and blue, film-coated tablets, each containing 5 mg chlordiazepoxide and 12.5 mg amitriptyline (as the hydrochloride salt)—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50.

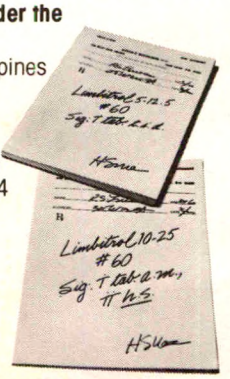
ROCHE®
ROCHE PRODUCTS INC.
Manati, Puerto Rico 00701

How to initiate and maintain therapy

Select dosage strength appropriate for each patient
☐ Limbitrol 5-12.5 is recommended to minimize drowsiness and for elderly patients
☐ Limbitrol 10-25 may be indicated for patients who tolerate medication without undue side effects

Specify daily dosage based on symptom severity
☐ An initial dosage of three tablets is recommended
☐ Dosage may be increased to six tablets or decreased to two tablets daily as necessary
☐ Once a satisfactory response is obtained, patients should be continued on the smallest dose required to maintain remission

Utilize dosage options to best accommodate individual patient needs
☐ T.I.D. or Q.I.D., familiar regimens most suited for patients who tolerate medication without undue drowsiness
☐ Two tablets one hour before bedtime and one tablet midday may minimize daytime drowsiness and help relieve a common target symptom—insomnia
☐ Entire dosage h.s. to take maximum advantage of the sedative effect



Your guide to patient management... when you decide medication is needed

How to make each patient an informed patient

1. Discuss with patients the probability that they will experience drowsiness, especially during the first week.
2. Reassure your patients that drowsiness is one indication that the medication is working and that it may help alleviate their insomnia.
3. Encourage patients to report if drowsiness becomes troublesome so that, if necessary, dosage schedule can be adjusted.
4. Caution patients about the combined effects with alcohol or other CNS depressants. Let them know that the additive effects may produce a harmful level of sedation and CNS depression.
5. Caution patients about activities requiring complete mental alertness, such as operating machinery or driving a car.
6. Warn pregnant patients and patients of childbearing age that the safety of Limbitrol in pregnancy has not yet been established.

Please see complete product disclosure for other pertinent information.

Limbitrol should not be used under the following circumstances:
1. Hypersensitivity to benzodiazepines or tricyclic antidepressants.
2. Concomitantly with an MAO inhibitor. To replace an MAO inhibitor with Limbitrol, discontinue MAO inhibitor for a minimum of 14 days before cautiously initiating Limbitrol therapy.
3. During the acute recovery phase following myocardial infarction.

In moderate depression and anxiety

The Brown Schools: Specialists in Residential Treatment

Residential treatment has become highly specialized in the field of mental health. It is a specific treatment modality for those who need a totally planned and structured environment.

The Brown Schools has developed a wide range of professional services that can be utilized to implement an individually planned residential treatment program. The degree of structure and protection, the intensity of therapy, the methods of education and training are controlled and modified with the resident's changing needs.

Professionals in the areas of psychiatry, psychology, nursing, social work, education, prevocational training, speech pathology, and recreation have developed expertise in the specific area of residential treatment. Each service area is designed as a component of an integrated therapeutic milieu.

The three residential treatment centers of The Brown Schools provide complete programming for those in need of twenty-four hour care. Services are available for children, adolescents, and adults with emotional disturbance, mental retardation, and neurological impairment. Two small group homes in Austin provide for reintegration into the community and complement the services offered in the other centers. For information, write:

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability ar insomnia associated with anxiety neuroses and transient situational disturbances; anxie associated with depressive symptoms and as a treatment of symptoms of anxiety if such sym toms are a significant feature of functional or organic disorders, particularly gastrointestinal cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by syster atic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CN acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with bart turates and alcohol have occurred following abrupt discontinuance of benzodiazepin (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addi tion-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillanc when on benzodiazepines because of their predisposition to habituation and dependenc Withdrawal symptoms have also been reported following abrupt discontinuance of benzod azepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid ov sedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occ sional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepa has not been shown of significant benefit in treating gastrointestinal or cardiovascular comp nent.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum huma therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn with 2 months of first observation. Clinical significance is unknown; but use of lorazepam for pr longed periods and in geriatric patients requires caution and frequent monitoring for symptor of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have h elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tes are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressa effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbi Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschis malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship dosage. Although all these anomalies were not present in the concurrent control group, th have been reported to occur randomly in historical controls. At 40mg/kg and higher, there w evidence of fetal resorption and increased fetal loss in rabbits which was not seen at low doses. Clinical significance of these findings is not known. However, increased risk of conge tal malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam a meprobamate) during first trimester of pregnancy has been suggested in several studi Because use of these drugs is rarely a matter of urgency, use of lorazepam during this peri should almost always be avoided. Possibility that a woman of child-bearing potential may pregnant at institution of therapy should be considered. Advise patients if they become pre nant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepa and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like oth benzodiazepines. As a general rule, nursing should not be undertaken while on a drug sin many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and genera disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxio patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9% weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, na sea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, e function disturbance, various gastrointestinal symptoms and autonomic manifestations. In dence of sedation and unsteadiness increased with age. Small decreases in blood pressu have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple age may have been taken. Manifestations of overdosage include somnolence, confusion and con Induce vomiting and/or undertake gastric lavage followed by general supportive care, monit ing of vital signs and close observation. Hypotension, though unlikely, usually may be control with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for Anxiety (lorazepam)

Dosage: **Individualize for maximum beneficial effects. Increase do gradually when needed, giving higher evening dose before increasi daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosa may vary from 1 to 10mg/day in divided doses. For elderly or deb tated, initially 1-2mg/day; insomnia due to anxiety or transient sit tional stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

Div. of AHPC, N.Y., N.Y. All rights rese

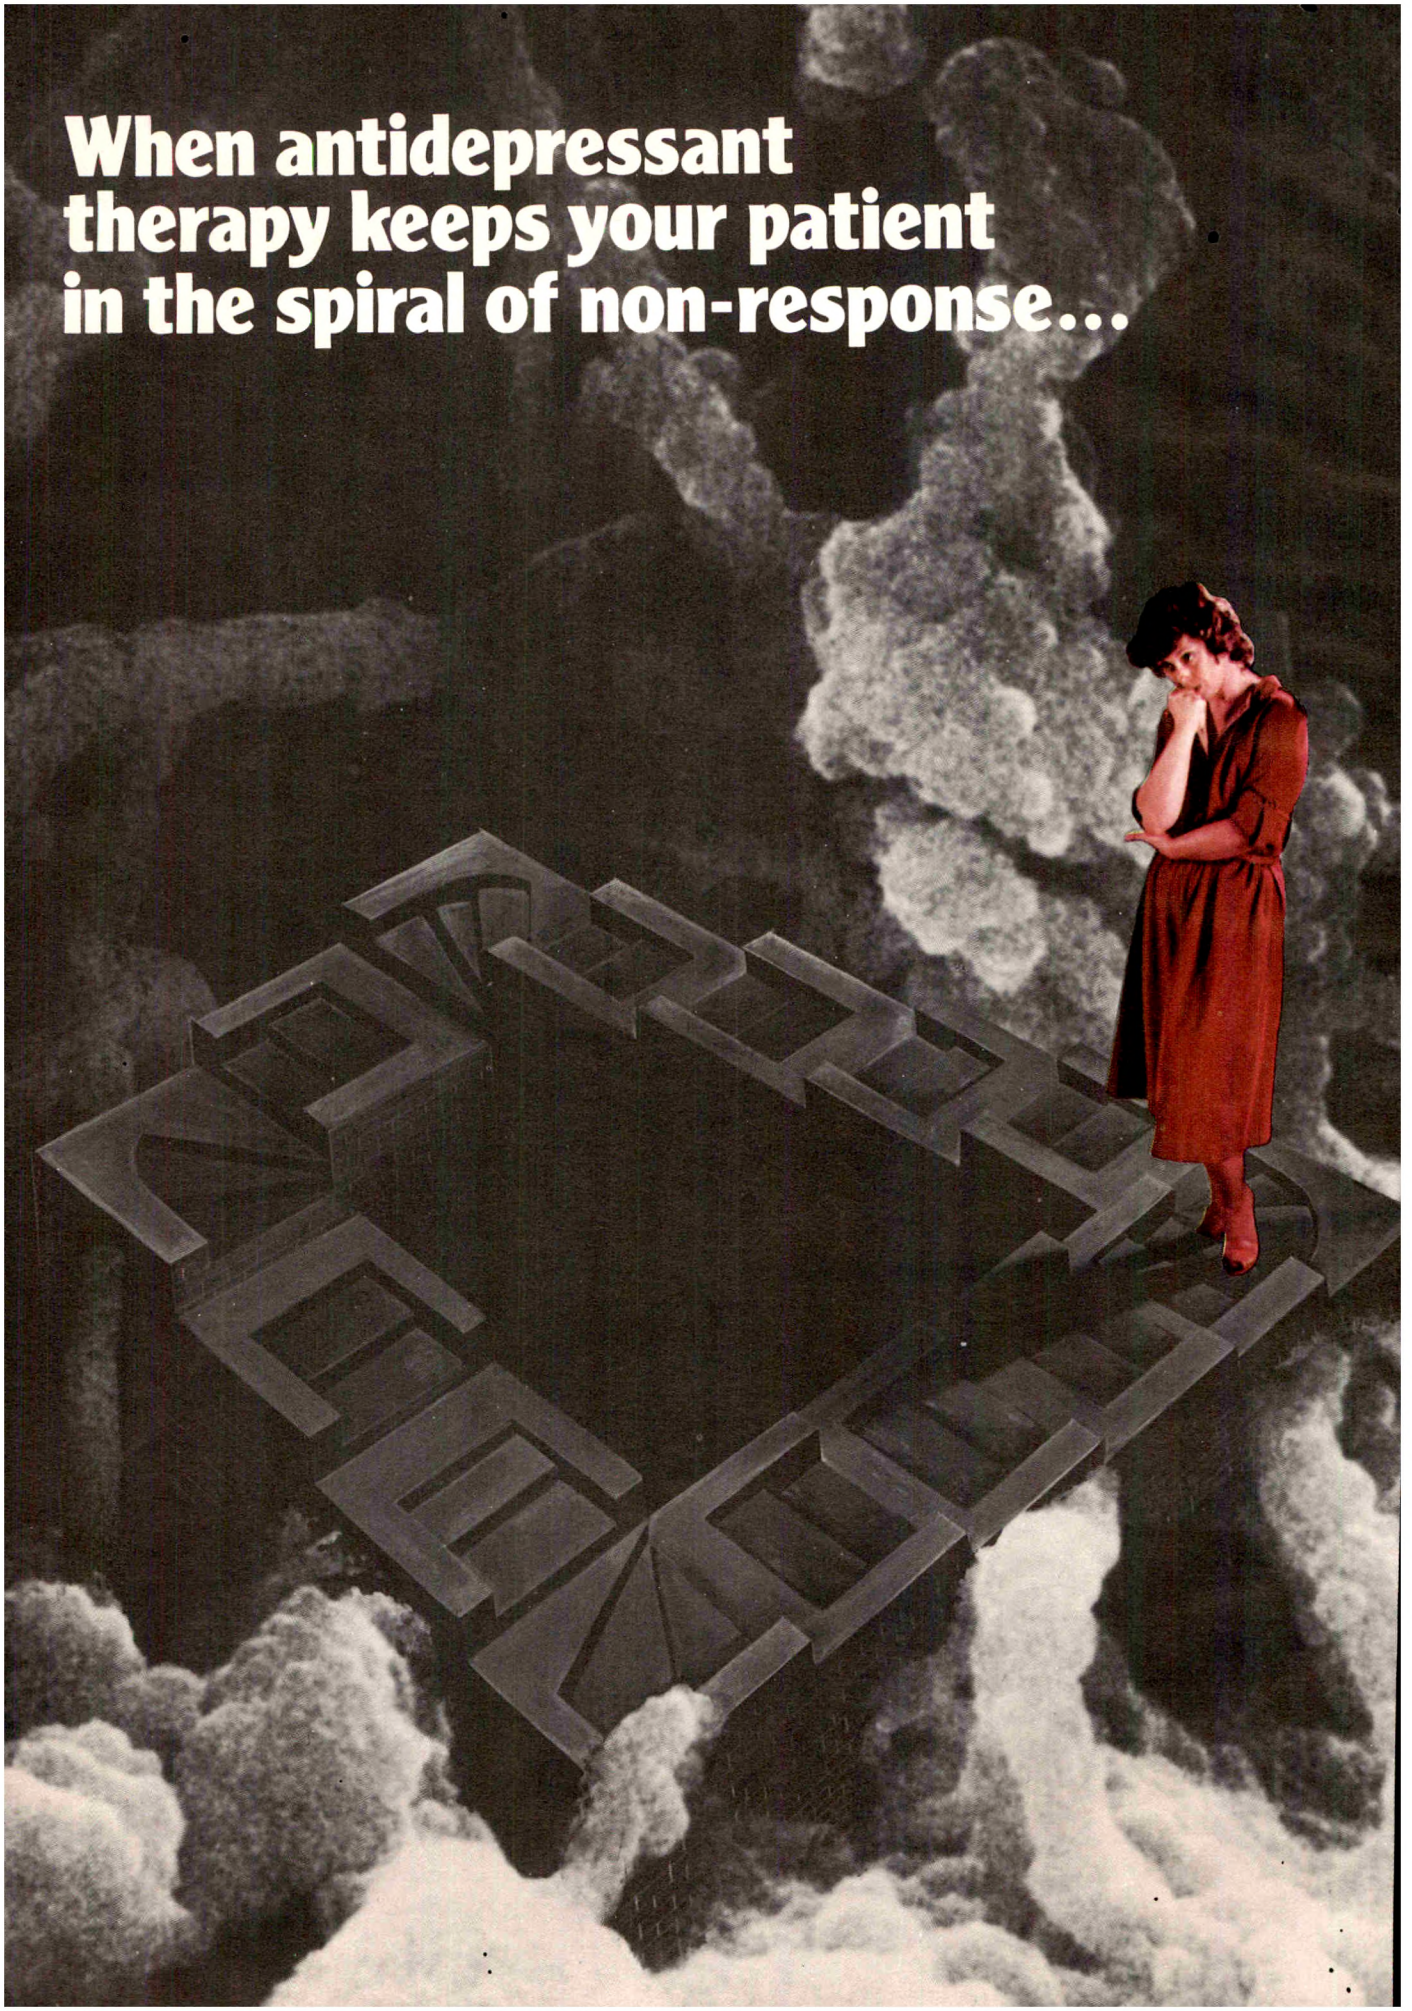
An age for anxiety.

The aging process all too frequently is accompanied by anxiety states. When anxious older patients do not respond to your sympathetic counseling, a benzodiazepine may be the next logical step.

But which one? Here, more than in many other patient groups, the metabolites of the available compounds may make a decisive difference. Unlike diazepam, clorazepate and chlordiazepoxide, Ativan (lorazepam) has no long-acting metabolites, and its simple metabolism is less readily impaired with advancing age. Steady-state serum levels are rapidly achieved and disappear rapidly once you decide to discontinue therapy. For these reasons, residual effects are not likely to present problems. (The pharmacokinetic profile of a drug can define such characteristics as its absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Proved effective in many nationwide, double-blind studies (including patients in older age groups), Ativan is compatible with a wide range of commonly prescribed drugs. (The benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.) Patients who have trouble swallowing solid medication appreciate the small Ativan tablet, which is tasteless and disintegrates within seconds in water or fruit juice.

See important information on preceding page.



Ativan® (lorazepam)

0.5 mg tablet

for Anxiety

COLLEGE OF MEDICINE
LIBRARY
U. C.

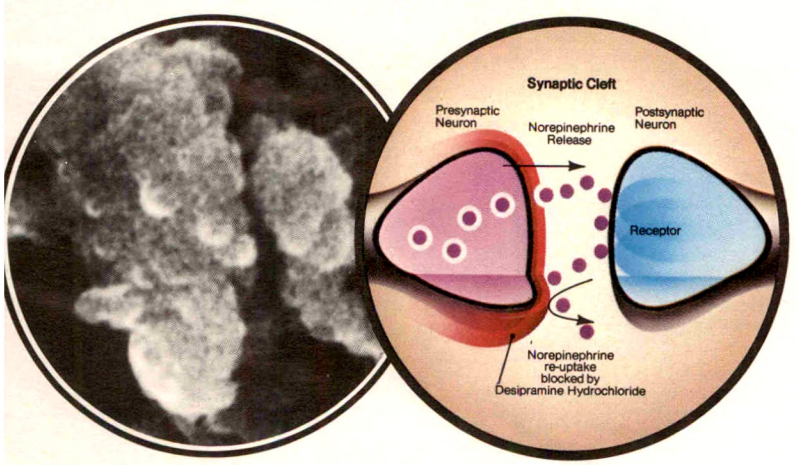
When antidepressant
therapy keeps your patient
in the spiral of non-response...

Consider changing to a tricyclic that blocks the re-uptake of a different neurotransmitter

Norpramin®

(desipramine hydrochloride tablets NF)

25, 50, 75, 100, 150 mg.



Helps the patient remain calm but active

- Begins to improve sleep patterns within one week in some patients.[1]
- As the depression is relieved, difficulty in falling asleep, restlessness, and early morning awakening diminish.
- Norpramin does not usually inhibit normal activity, although patients should be cautioned against driving or operating machinery if drowsiness occurs. (See Warnings, Precautions, and Adverse Reactions in Brief Summary overleaf.)

Less anticholinergic activity

- Studies of animal tissues[2] and normal human subjects[3,4] have shown that desipramine has less anticholinergic activity than amitriptyline or doxepin.
- The single-bond side chain of desipramine may be associated with less anticholinergic activity than is the double-bond side chain of amitriptyline or doxepin.
- This may mean less dry mouth, less blurred vision, less urinary retention.

(See Warnings in Brief Summary overleaf.)

lectron micrograph of human synaptic left, postulated site of tricyclic ntidepressant activity.

Laboratory evidence suggests that desipramine blocks the re-uptake of norepinephrine at the presynaptic nerve terminal,[7] ensuring increased cleft and receptor site neurotransmitter concentration.

Potent blocker of norepinephrine re-uptake

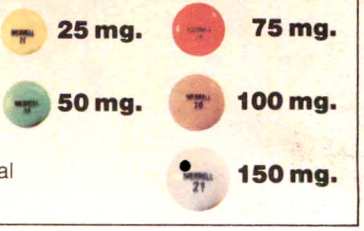
Current evidence[5,6] suggests depression results from inadequate levels of norepinephrine or serotonin here, at the synaptic cleft.

If your patient is unresponsive to treatment with one tricyclic, consider switching to a tricyclic that blocks the re-uptake of a different neurotransmitter.

(Please read the Brief Summary overleaf before prescribing Norpramin.)

Merrell

MNQ-266



☐ potent blocker of norepinephrine re-uptake

☐ with improved sleep patterns beginning within one week in some patients[1]

☐ with less anticholinergic activity than amitriptyline or doxepin, as shown in studies of animal tissues[2] and normal human subjects[3,4] (See Warnings section of Brief Summary.)

Dosage Flexibility

Convenient choice of 5 tablet strengths and once daily or divided dosage schedule allows titration to individual response.

Norpramin®
(desipramine hydrochloride tablets NF)

AVAILABLE ONLY ON PRESCRIPTION

Brief Summary

MECHANISM OF ACTION: Available evidence suggests that many depressions have a biochemical basis in the form of a relative deficiency of neurotransmitters such as norepinephrine and serotonin. Norepinephrine deficiency may be associated with relatively low urinary 3-methoxy-4-hydroxyphenyl glycol (MHPG) levels, while serotonin deficiencies may be associated with low spinal fluid levels of 5-hydroxyindolacetic acid.

While the precise mechanism of action of the tricyclic antidepressants is unknown, a leading theory suggests that they restore normal levels of neurotransmitters by blocking the re-uptake of these substances from the synapse in the central nervous system.

Evidence indicates that the secondary amine tricyclic antidepressants, including Norpramin, may have greater activity in blocking the re-uptake of norepinephrine. Tertiary amine tricyclic antidepressants, such as amitriptyline, may have greater effect on serotonin re-uptake.

Norpramin (desipramine hydrochloride) is not a monoamine oxidase (MAO) inhibitor and does not act primarily as a central nervous system stimulant. It has been found in some studies to have a more rapid onset of action than imipramine. Earliest therapeutic effects may occasionally be seen in 2 to 5 days, but full treatment benefit usually requires 2 to 3 weeks to obtain.

INDICATIONS: Norpramin (desipramine hydrochloride) is indicated for relief of symptoms in various depressive syndromes, especially endogenous depression.

CONTRAINDICATIONS: Desipramine hydrochloride should not be given in conjunction with, or within 2 weeks of, treatment with an MAO inhibitor drug; hyperpyretic crises, severe convulsions, and death have occurred in patients taking MAO inhibitors and tricyclic antidepressants. When Norpramin (desipramine hydrochloride) is substituted for an MAO inhibitor, at least 2 weeks should elapse between treatments. Norpramin should then be started cautiously and should be increased gradually.

The drug is contraindicated in the acute recovery period following myocardial infarction. It should not be used in those who have shown prior hypersensitivity to the drug. Cross sensitivity between this and other dibenzazepines is a possibility.

WARNINGS: 1. Extreme caution should be used when this drug is given in the following situations: a. In patients with cardiovascular disease, because of the possibility of conduction defects, arrhythmias, tachycardias, strokes, and acute myocardial infarction. b. In patients with a history of urinary retention or glaucoma, because of the anticholinergic properties of the drug. c. In patients with thyroid disease or those taking thyroid medication, because of the possibility of cardiovascular toxicity, including arrhythmias. d. In patients with a history of seizure disorder, because this drug has been shown to lower the seizure threshold. **2.** This drug is capable of blocking the antihypertensive effect of guanethidine and similarly acting compounds. **3.** USE IN PREGNANCY: Safe use of desipramine hydrochloride during pregnancy and lactation has not been established; therefore, if it is to be given to pregnant patients, nursing mothers, or women of childbearing potential, the possible benefits must be weighed against the possible hazards to mother and child. Animal reproductive studies have been inconclusive. **4.** USE IN CHILDREN: Norpramin (desipramine hydrochloride) is not recommended for use in children since safety and effectiveness in the pediatric age group have not been established. **5.** The patient should be cautioned that this drug may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery. **6.** In patients who may use alcohol excessively, it should be borne in mind that the potentiation may increase the danger inherent in any suicide attempt or overdosage.

PRECAUTIONS: 1. It is important that this drug be dispensed in the least possible quantities to depressed outpatients, since suicide has been accomplished with this class of drug. Ordinary prudence requires that children not have access to this drug or to potent drugs of any kind; if possible this drug should be dispensed in containers with child-resistant safety closures. Storage of this drug in the home must be supervised responsibly. **2.** If serious adverse effects occur, dosage should be reduced or treatment should be altered. **3.** Norpramin (desipramine hydrochloride) therapy in patients with manic-depressive illness may induce a hypomanic state after the depressive phase terminates. **4.** The drug may cause exacerbation of psychosis in schizophrenic patients. **5.** Close supervision and careful adjustment of dosage are required when this drug is given concomitantly with anticholinergic or sympathomimetic drugs. **6.** Patients should be warned that while taking this drug their response to alcoholic beverages may be exaggerated. **7.** Clinical experience in the concurrent administration of ECT and antidepressant drugs is limited. Thus, if such treatment is essential, the possibility of increased risk relative to benefits should be considered. **8.** The sedative effects of Norpramin and benzodiazepines (*e.g.*, chlordiazepoxide or diazepam) are additive. Both the sedative and anticholinergic effects of the major tranquilizers are additive to those of Norpramin. **9.** This drug should be discontinued as soon as possible prior to elective surgery because of the possible cardiovascular effects. Hypertensive episodes have been observed during surgery in patients taking desipramine hydrochloride. **10.** Both elevation and lowering of blood sugar levels have been reported. **11.** Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathologic neutrophil depression. **12.** Norpramin 25, 50, 75, and 100 mg. tablets contain FD&C Yellow No. 5 (tartrazine), which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

ADVERSE REACTIONS: NOTE: Included in the following listing are a few adverse reactions that have not been reported with this specific drug. However, the pharmacologic similarities among the tricyclic antidepressant drugs require that each of the reactions be considered when Norpramin (desipramine hydrochloride) is given.

Cardiovascular: hypotension, hypertension, tachycardia, palpitation, arrhythmias, heart block, myocardial infarction, stroke.

Psychiatric: confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurologic: numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures; alteration in EEG patterns; tinnitus.

Anticholinergic: dry mouth, and rarely associated sublingual adenitis; blurred vision, disturbance of accommodation, mydriasis, increased intraocular pressure; constipation, paralytic ileus; urinary retention, delayed micturition, dilatation of urinary tract.

Allergic: skin rash, petechiae, urticaria, itching, photosensitization (avoid excessive exposure to sunlight), edema (of face and tongue or general), drug fever, cross sensitivity with other tricyclic drugs.

Hematologic: bone marrow depressions including agranulocytosis, eosinophilia, purpura, thrombocytopenia.

Gastrointestinal: anorexia, nausea and vomiting, epigastric distress, peculiar taste, abdominal cramps, diarrhea, stomatitis, black tongue.

Endocrine: gynecomastia in the male, breast enlargement and galactorrhea in the female; increased or decreased libido, impotence, testicular swelling; elevation or depression of blood sugar levels.

Other: jaundice (simulating obstructive), altered liver function; weight gain or loss; perspiration, flushing; urinary frequency, nocturia; parotid swelling; drowsiness, dizziness, weakness and fatigue, headache; alopecia.

Withdrawal Symptoms: Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

DOSAGE AND ADMINISTRATION: Not recommended for use in children. Lower dosages are recommended for elderly patients and adolescents. Lower dosages are also recommended for outpatients compared to hospitalized patients, who are closely supervised. Dosage should be initiated at a low level and increased according to clinical response and any evidence of intolerance. Following remission, maintenance medication may be required for a period of time and should be at the lowest dose that will maintain remission.

Usual Adult Dose: The usual adult dose is 100 to 200 mg. per day. In more severely ill patients, dosage may be further increased gradually to 300 mg./day if necessary. Dosages above 300 mg./day are not recommended.

Dosage should be initiated at a lower level and increased according to tolerance and clinical response.

Treatment of patients requiring as much as 300 mg. should generally be initiated in hospitals, where regular visits by the physician, skilled nursing care, and frequent electrocardiograms (ECG's) are available.

The best available evidence of impending toxicity from very high doses of Norpramin is prolongation of the QRS or QT intervals on the ECG. Prolongation of the PR interval is also significant, but less closely correlated with plasma levels. Clinical symptoms of intolerance, especially drowsiness, dizziness, and postural hypotension, should also alert the physician to the need for reduction in dosage. Plasma desipramine measurement would constitute the optimal guide to dosage monitoring.

Initial therapy may be administered in divided doses or a single daily dose.

Maintenance therapy may be given on a once-daily schedule for patient convenience and compliance.

Adolescent and Geriatric Dose: The usual adolescent and geriatric dose is 25 to 100 mg. daily.

Dosage should be initiated at a lower level and increased according to tolerance and clinical response to a usual maximum of 100 mg. daily. In more severely ill patients, dosage may be further increased to 150 mg./day. Doses above 150 mg./day are not recommended in these age groups.

Initial therapy may be administered in divided doses or a single daily dose.

Maintenance therapy may be given on a once-daily schedule for patient convenience and compliance.

OVERDOSAGE: See prescribing information for a discussion of symptoms and treatment of overdose.

Product Information as of July, 1979

LAWYERS, PSYCHIATRISTS AND CRIMINAL LAW

Cooperation or Chaos?

By **Harlow M. Huckabee,** *Arlington, Virginia. Foreword by* **Fred G. Folsom** *and* **Cono R. Namorato.** This law-psychiatry interface brings together and analyzes the conflicting positions and theories related to criminal responsibility and competency to stand trial.

The first of two main sections focuses on criminal responsibility and the controversy generated by that topic among professionals. Among the areas reviewed are responsibility tests, evidence of mental disorder on *mens rea* the mental state required for the offense), various proposals to substitute *mens rea* for traditional responsibility tests, and the current chaos and need for cooperation among psychiatrists and lawyers. In the concluding chapter of this section, the author suggests the establishment of a research/clearinghouse program that would coordinate efforts to solve problems at both the state and federal levels.

The second section evaluates a number of other problems related to law and psychiatry. Competency to stand trial, the debate on psychiatrists' expertise in matters of criminal law, the briefing of psychiatrists, shopping for psychiatrists, and the use of impartial experts and/or court psychiatric clinics are all analyzed.

This volume points to the factors affecting psychiatric opinions and describes how psychiatrists can arrive at opposite conclusions concerning the same defendant; clarifies the culpability of courts and lawyers, as well as psychiatrists, for the breakdown in the system; and demonstrates the criticality of lawyer-psychiatrist cooperation. Its inclusion of suggestions for further research and action in this area adds to the importance of this work. *'80, 184 pp., $16.75*

New! **PRIMER ON THE RORSCHACH TECHNIQUE: A Method of Administration, Scoring, and Interpretation** *by* **Eugene E. Levitt,** *Indiana Univ. School of Medicine, Indianapolis.* Special features include a step-by-step format, a discussion of methods for correlating the Rorschach with the MMPI, and a chapter on the use of the Rorschach technique with children. Appendices present information on the probabilities of the use of color as a determinant in selected responses, scoring illustrations, and interpretation of individual Rorschach factors. *'80, 116 pp., 2 il., 15 tables, cloth-$14.50, paper-$8.95*

THE AMERICAN ALCOHOLIC: The Nature-Nurture Controversy in Alcoholic Research and Therapy (3rd Ptg.) *by* **William Madsen,** *Univ. of California, Santa Barbara. '80, 272 pp., 4 il., $14.50*

New! **LEGAL PSYCHOLOGY: Eyewitness Testimony-Jury Behavior** *by* **L. Craig Parker, Jr.,** *Univ. of New Haven, West Haven, Connecticut. '80, 196 pp., $22.75*

New! **APPLICATION OF HYPNOSIS IN SEX THERAPY** *by* **Hugo G. Beigel** *and* **Warren R. Johnson,** *Univ. of Maryland, College Park. (13 Contributors)* Following a discussion of the exploratory techniques of sex hypnotherapy, hypnotherapeutic procedures are presented for such sexual disorders as anorgasmia, frigidity, vaginismus, primary and secondary impotence, and premature ejaculation. Numerous case studies are included. Appendices detail the authors' favorite induction techniques and the legal aspects of practicing hypnosis. *'80, 352 pp., 1 table, $29.75*

New! **TRANSSEXUALITY IN THE MALE: The Spectrum of Gender Dysphoria** *by* **Erwin K. Koranyi,** *Univ. of Ottawa, Ottawa, Ontario, Canada. Foreword by* **Ralph Slovenko.** *(3 Contributors)* A wide range of topics related to transsexuality in the male is herein explored, including the interplay of biological and psychological factors, sexual dimorphism, natural sex change, genetics and sexuality, medicolegal considerations, surgical procedures, and hormonal and psychosocial treatments. A glossary and bibliography follow the text. *'80, 192 pp., 31 il., 1 table, $17.50*

New! **BECOMING A WOMAN: The Socialization of Gender** *by* **Bernice Lott,** *Univ. of Rhode Island, Kingston.* This book analyzes the female experience from conception through old age and scrutinizes aspects of the socialization process common to American women. Among the topics discussed are the nature and nurture of the female infant, socialization in childhood, love and marriage, rape and physical abuse, motherhood, work, and menopause. *'80, 464 pp., 6 il., cloth-$24.75, paper-$18.50*

New! **BODYMIND LIBERATION: Achieving Holistic Health** *by* **Robert Henley Woody,** *Univ. of Nebraska, Omaha.* The author of this text explains how the integration of physical and mental processes determines the overall health of the human organism. He shows how the bodymind operates, how bodymind problems occur, and how the bodymind can be liberated and restored to health through pragmatic techniques. The necessity of controlling anxiety; the significance of self-actualization; the effects of trust, caring, and sharing; the value of physical contact; and related subjects are examined. *'80, 172 pp., $15.50*

New! **GRIEF COUNSELING AND SUDDEN DEATH: A Manual and Guide** *by* **Polly Doyle,** *Contra Costa County Crisis and Suicide Intervention Center, Walnut Creek, California. (8 Contributors)* Not only does this book provide the information needed to understand grief and to counsel bereaved persons, it also details the development and operation of a community-based, volunteer grief counseling program. An extensive section on general counseling techniques and approaches covers such specifics as the anniversary interview, the role of the Coroner's Office, the autopsy, and the funeral. *'80, 336 pp., 1 il., $21.50*

New! **COUNSELING THE ELDERLY: For Professional Helpers Who Work with the Aged** *edited by* **Garry L. Landreth** *and* **Robert C. Berg,** *both of North Texas State Univ., Denton. (64 Contributors) '80, 484 pp., 10 il., 13 tables, cloth-$26.75, paper-$19.75*

New! **IMPROVING EFFECTIVENESS AND REDUCING COSTS IN MENTAL HEALTH** *by* **Brian T. Yates,** *American Univ., Washington, D. C. Foreword by* **Frederick L. Newman.** *'80, 240 pp., 31 il., 42 tables, $19.75*

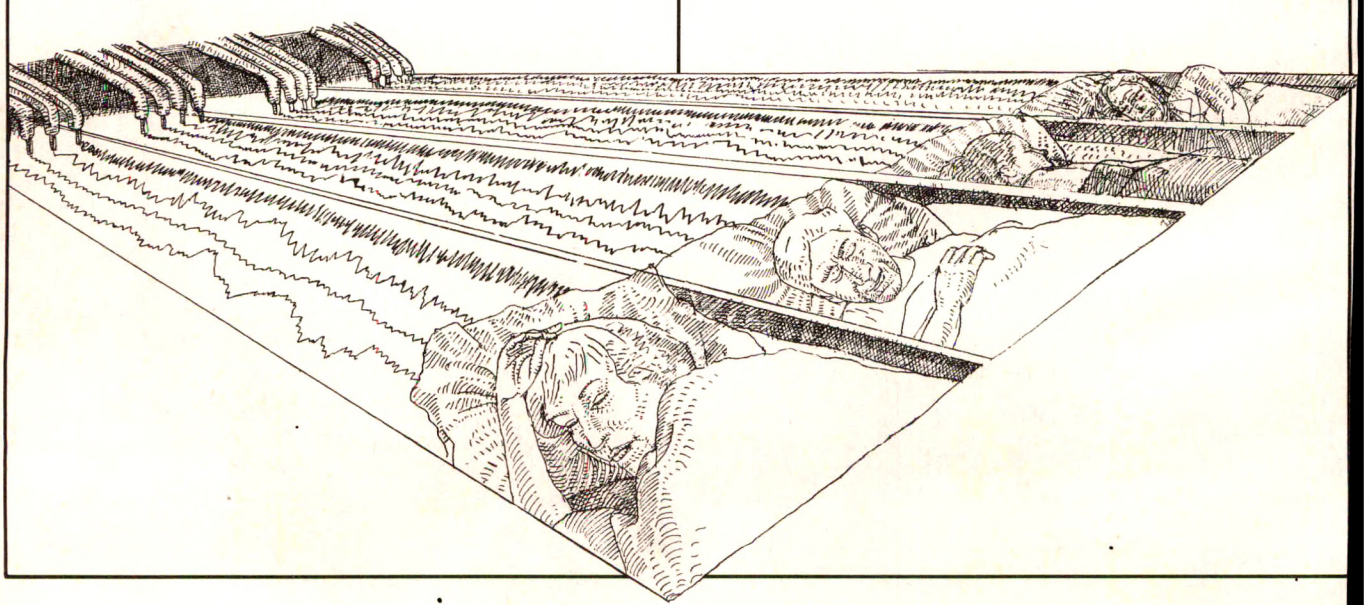
DALMANE
(flurazepam HCl/Roche

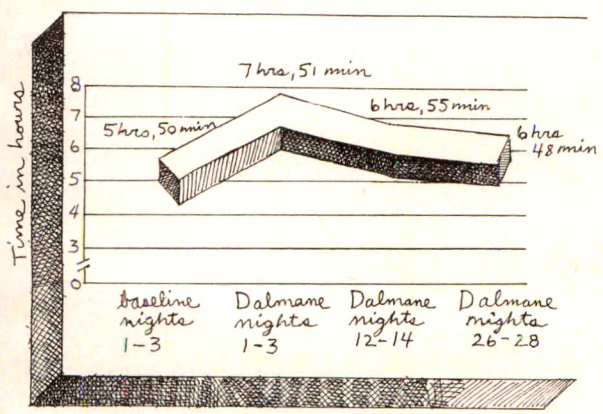


MORE POLYGRAPHIC EVIDENCE

Sleep research laboratory testing of insomnia patients for 995 subject nights demonstrates efficacy of Dalmane (flurazepam HCl/Roche)[1]

In 14 separate studies, subjects given Dalmane were monitored with polygraphic recordings for a total of 995 nights, objectively demonstrating the efficacy of Dalmane.

Efficacy from the first night through 28 nights, without need to increase dosage



Dalmane (flurazepam HCl/Roche) is the only sleep medication objectively proven effective through 28 consecutive nights of administration in two separate studies in the sleep research laboratory.[2-4] The prolonged use of Dalmane is seldom necessary; should it be, appropriate patient evaluations such as periodic blood counts and liver and kidney function tests are recommended.

)FFERS

)F EFFICACY FOR INSOMNIA

Dalmane® (flurazepam HCl/Roche) improved sleep during short, intermediate and longer-term use

Improvement shown represents mean improvement, in hours, of total sleep time. n=5

Adapted from Dement WC, *et al: Behav Med* 5:25-31, Oct 1978

Since most insomnia is transitory in nature, initiate therapy at the lowest effective dose for the shortest time advisable to achieve a predetermined therapeutic goal.

References:
1. Data on file, Medical Department, Hoffmann-La Roche Inc., Nutley NJ
2. Kales A, *et al: Clin Pharmacol Ther 19:* 576-583, May 1976
3. Dement WC, *et al: Behav Med* 5: 25-31, Oct 1978
4. Kales A, *et al: Clin Pharmacol Ther 18:* 356-363, Sep 1975

Clinical documentation of efficacy in 4950 patients with insomnia[1]

Dalmane (flurazepam HCl/Roche) efficacy was evaluated in 18 clinical studies. These included paired-night, double-blind crossover, double-blind comparison and patient preference studies. Results of these studies demonstrated and confirmed the effectiveness of Dalmane.

Periodic evaluation of patient's sleep habits may help prevent subsequent insomnia

Should insomnia recur, the patient may need guidance in setting up a regular sleep program. This may include establishment of a regular bedtime hour, taking a warm bath prior to retiring and avoidance of alcohol, stimulants or heavy meals late in the evening.

DALMANE® (IV)

flurazepam HCl/Roche
15-mg and 30-mg capsules

UNMATCHED PROOF, UNMATCHED EFFICACY

Please see summary of product information on following page.

ROCHE®

Protocol for insomnia management

☐ Treat physical and/or psychological factors that may underlie an inability to sleep.

☐ Thoroughly question and evaluate new patients who specifically request sleep medications.

☐ Consider other medications the patient may be taking (including alcoholic beverages) and be aware of possible drug interactions.

☐ Select a sleep medication with objectively *documented* proof of efficacy and a wide margin of safety.

☐ Initiate treatment at the lowest effective dose for the period of time deemed necessary *to achieve a reasonable therapeutic goal.*

☐ Monitor response to therapy and, based upon patient reassessment, determine need for continuing medication on an individual basis.

☐ Advise patients who ingest alcoholic beverages or other CNS depressants against doing so while on sleep medication. CNS stimulants such as caffeine should also be discontinued.

☐ Caution patients against engaging in hazardous occupations requiring complete mental alertness such as operating machinery or driving a motor vehicle shortly after ingesting the drug. In addition, as with all CNS depressants, patients may have reduced motor performance while on hypnotic therapy and should be advised accordingly.

☐ Avoid prescribing for suicidal or dependency-prone individuals whose histories indicate an inability to handle any psychoactive substances including alcohol.

Now available from Roche—important guidance for your patients with insomnia.

DA-5T

DALMANE® (IV)
flurazepam HCl/Roche

One 15-mg capsule *h.s.*—recommended initial dosage for elderly or debilitated patients.
One 30-mg capsule *h.s.*—usual adult dosage
(15 mg may suffice in some patients).

Before prescribing, please consult complete product information, a summary of which follows:
Indications: Effective in all types of insomnia characterized by difficulty in falling asleep, frequent nocturnal awakenings and/or early morning awakening; in patients with recurring insomnia or poor sleeping habits; in acute or chronic medical situations requiring restful sleep. Objective sleep laboratory data have shown effectiveness for at least 28 consecutive nights of administration. Since insomnia is often transient and intermittent, prolonged administration is generally not necessary or recommended.
Contraindications: Known hypersensitivity to flurazepam HCl.
Warnings: Caution patients about possible combined effects with alcohol and other CNS depressants. Caution against hazardous occupations requiring complete mental alertness (*e.g.*, operating machinery, driving).

Usage in Pregnancy: **Several studies of minor tranquilizers (chlordiazepoxide, diazepam, and meprobamate) suggest increased risk of congenital malformations during the first trimester of pregnancy. Dalmane, a benzodiazepine, has not been studied adequately to determine whether it may be associated with such an increased risk. Because use of these drugs is rarely a matter of urgency, their use during this period should almost always be avoided. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Not recommended for use in persons under 15 years of age. Though physical and psychological dependence have not been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage.
Precautions: In elderly and debilitated patients, it is recommended that the dosage be limited to 15 mg to reduce risk of oversedation, dizziness, confusion and/or ataxia. Consider potential additive effects with other hypnotics or CNS depressants. Employ usual precautions in patients who are severely depressed, or with latent depression or suicidal tendencies, or with impaired renal or hepatic function. Periodic blood counts and liver and kidney function tests are advised during repeated therapy.
Adverse Reactions: Dizziness, drowsiness, lightheadedness, staggering, ataxia and falling have occurred, particularly in elderly or debilitated patients. Severe sedation, lethargy, disorientation and coma, probably indicative of drug intolerance or overdosage, have been reported. Also reported: headache, heartburn, upset stomach, nausea, vomiting, diarrhea, constipation, GI pain, nervousness, talkativeness, apprehension, irritability, weakness, palpitations, chest pains, body and joint pains and GU complaints. There have also been rare occurrences of leukopenia, granulocytopenia, sweating, flushes, difficulty in focusing, blurred vision, burning eyes, faintness, hypotension, shortness of breath, pruritus, skin rash, dry mouth, bitter taste, excessive salivation, anorexia, euphoria, depression, slurred speech, confusion, restlessness, hallucinations, paradoxical reactions, *e.g.*, excitement, stimulation and hyperactivity, and elevated SGOT, SGPT, total and direct bilirubins and alkaline phosphatase.
Dosage: Individualize for maximum beneficial effect.
Adults: 30 mg usual dosage; 15 mg may suffice in some patients.
Elderly or debilitated patients: 15 mg recommended initially until response is determined.
Supplied: Capsules containing 15 mg or 30 mg flurazepam HCl.

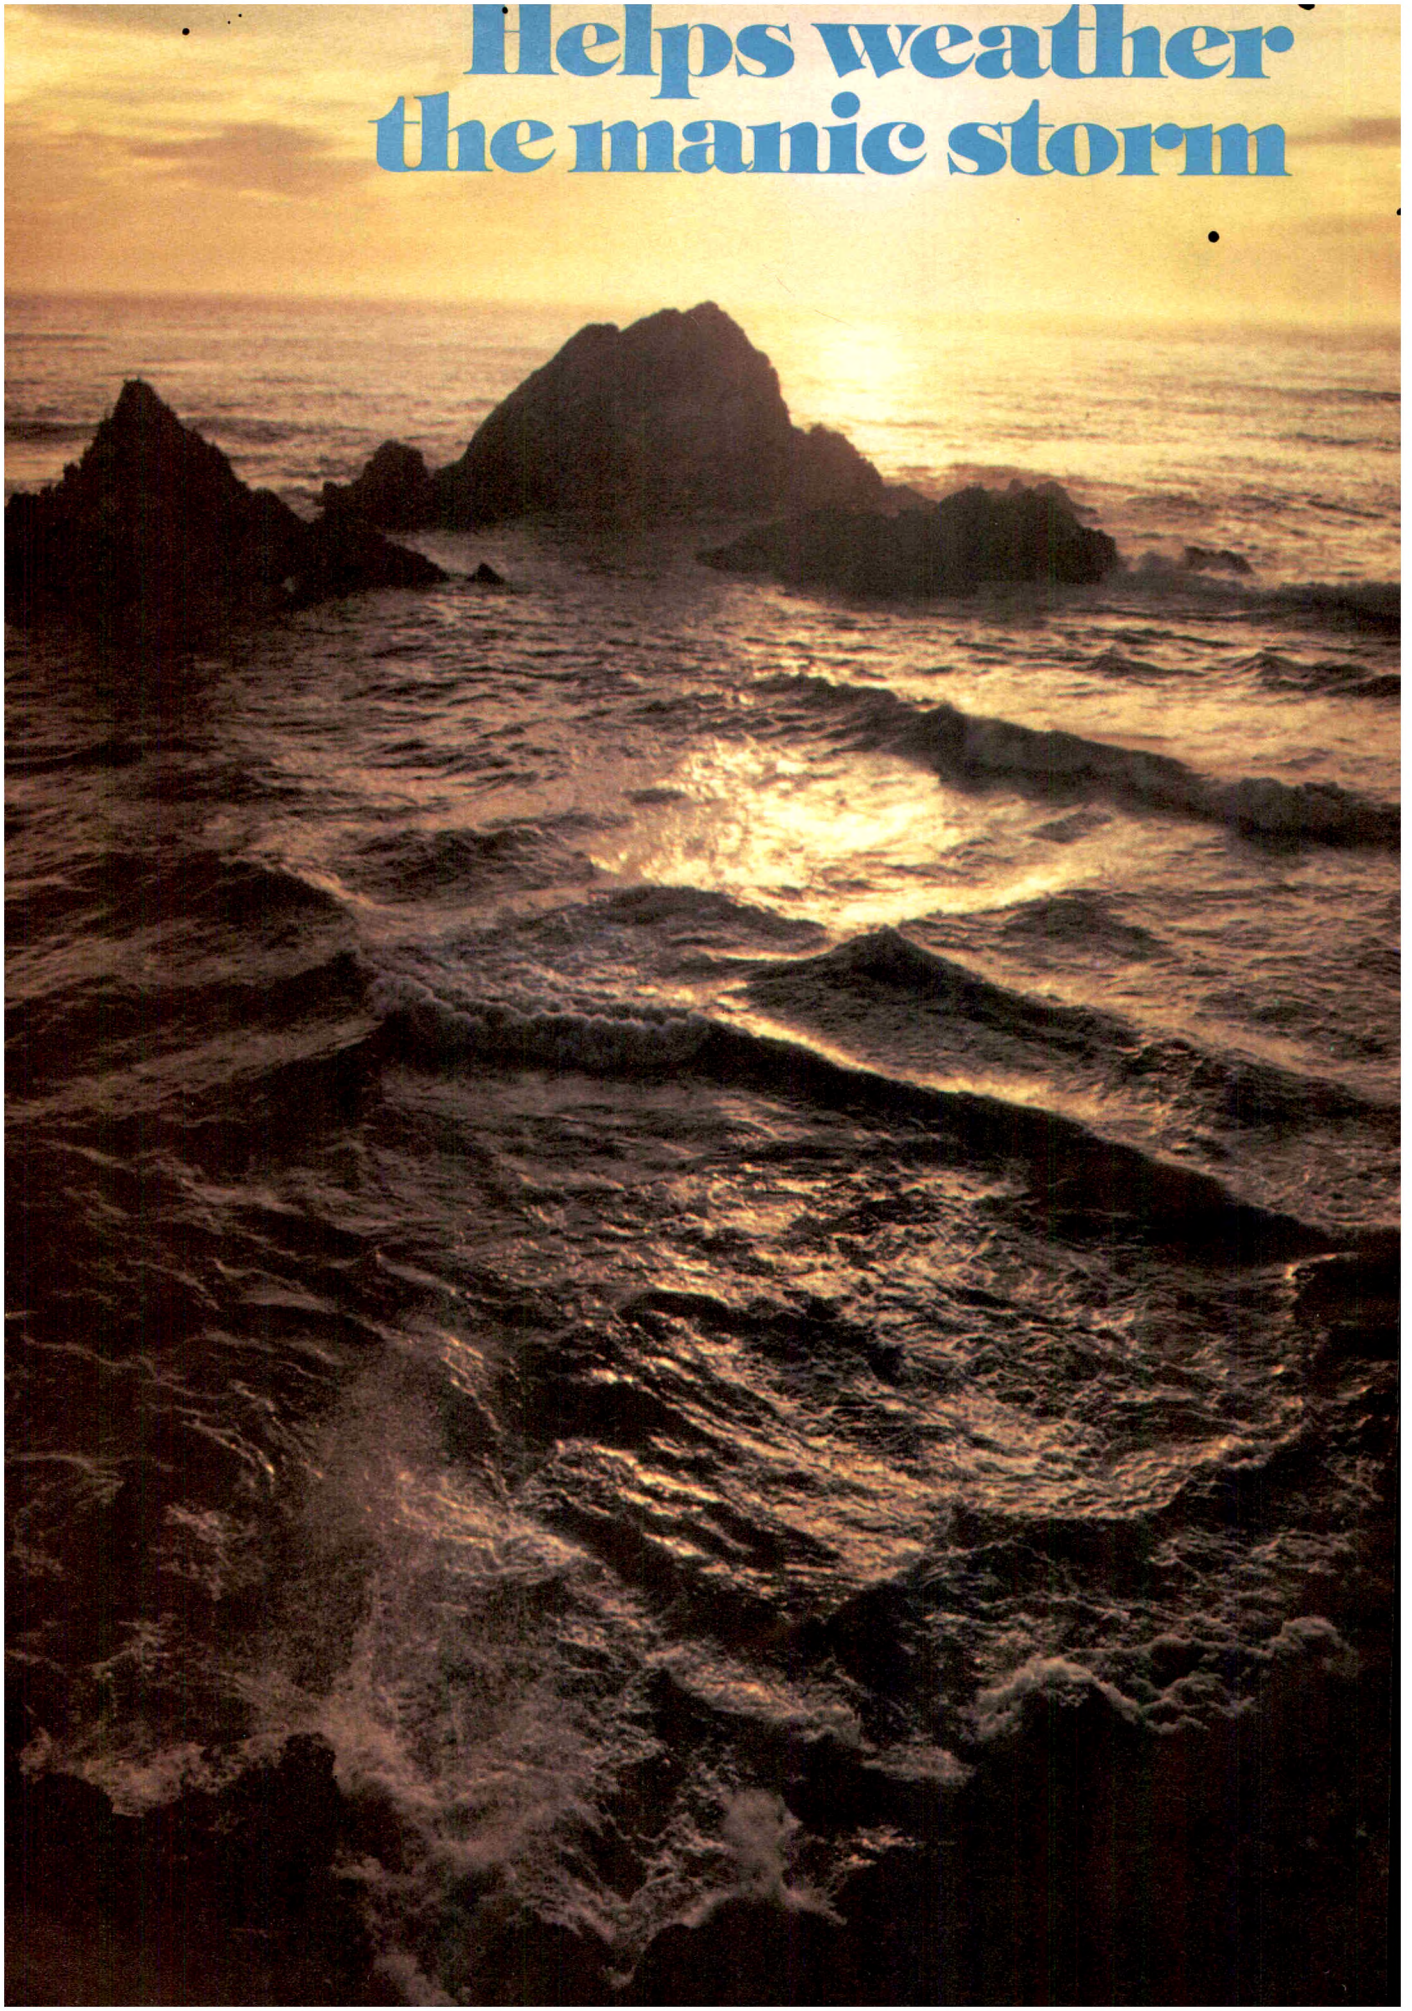
The B24 III...a new generation of electro-convulsive therapy instrumentation from Medcraft.

UL LISTED

Designed with patient and operator safety in mind, this new series of instrumentation meets the rigorous requirements for listing by Underwriters Laboratories — UL 544, Standards for Medical and Dental Equipment. The B24 III provides the physician with the ultimate in precision dosage levels. Consistancy of desired output level is assured with the following features:



- Line Voltage Compensation — allows compensation for fluctuations in incoming line voltages.
- Pre-programmed Voltage Selection — choice of eleven voltage levels from 70 volts to 170 volts.
- Automatic Treatment Timing — adjustable from 0.1 second to 1.0 second with or without Glissando.
- Current Output Indicators — visual assurance of current flow during treatment.

Exclusive Patient Test Module allows a complete systems integrity check of insturmentation prior to treatment. Clinical accuracy and dependability are assured by the use of 100% solid state circuitry. Double shielded transformer provides an additional margin of treatment safety. Write or call for ordering information, specifications and prices.

Helps weather
the manic storm

maintenance therapy with Eskalith®

brand of

lithium carbonate

300 mg capsules and
300 mg scored tablets

In manic-depressive patients with a history of mania, 'Eskalith'

- prevents or diminishes the intensity of future episodes
- can increase the intervals between episodes
- helps patients function within normal limits

Before prescribing, see complete prescribing information in SK&F literature or PDR. The following is a brief summary.

WARNING
Lithium toxicity is closely related to serum lithium levels, and can occur at doses close to therapeutic levels. Facilities for prompt and accurate serum lithium determinations should be available before initiating therapy.

Indications: Treatment of manic episodes of manic-depressive illness. Maintenance therapy prevents or diminishes the intensity of subsequent episodes in manic-depressive patients with a history of mania.

Warnings: Lithium should generally not be given to patients with significant renal or cardiovascular disease, severe debilitation or dehydration, sodium depletion, or to patients receiving diuretics.

Chronic lithium therapy may be associated with diminution of renal concentrating ability; such patients should be carefully managed to avoid dehydration with resulting lithium retention and toxicity. Morphologic changes with glomerular and interstitial fibrosis and nephron atrophy have been reported. When renal function is assessed, progressive or sudden changes in function indicate the need for reevaluation of treatment.

Caution patient and family to watch for diarrhea, vomiting, tremor, mild ataxia, drowsiness, or muscular weakness as signs of lithium toxicity, and to discontinue therapy and contact a physician should they occur. Patients receiving combined therapy with lithium and an antipsychotic should be monitored closely for early evidence of neurologic toxicity and treatment discontinued promptly if such signs appear. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery).

Lithium may prolong the effects of neuromuscular blocking agents. Such agents should be given with caution to patients receiving lithium.

Lithium may cause fetal developmental anomalies, especially involving the cardiovascular system. If lithium is used during pregnancy, or if a patient becomes pregnant while taking it, she should be apprised of the potential hazard to the fetus. Except in rare and unusual circumstances, nursing should not be undertaken while a patient is on lithium therapy, since lithium is excreted in human milk.

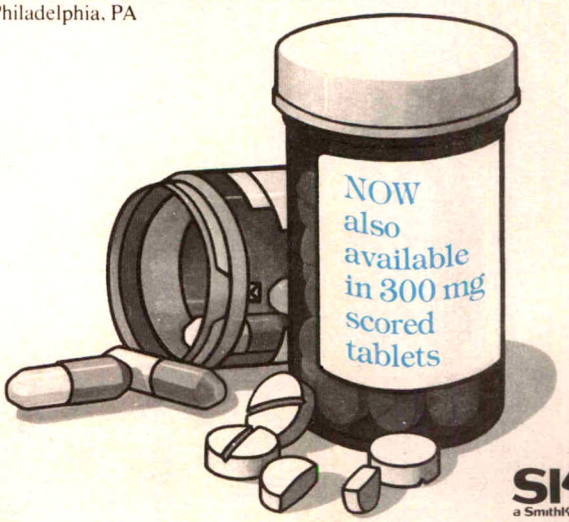
Not recommended for children under 12.

Precautions: Lithium tolerance is greater during the acute manic phase and decreases when manic symptoms subside.

Lithium therapy may lead to sodium depletion. Normal diet (including salt) and adequate fluid intake (2500-3000 ml.) must be maintained, at least during initial stabilization period. Protracted sweating or diarrhea can decrease tolerance; in such cases, administer supplemental fluid and salt.

Sweating, diarrhea, and concomitant infection with elevated temperatures may require temporary reduction or cessation of dosage.

Where hypothyroidism exists, thyroid function should be monitored during lithium stabilization and maintenance; where hypothyroidism occurs during stabilization and maintenance, supplemental thyroid treatment may be used.



Adverse Reactions: Mild to moderate toxic reactions may occur at serum lithium levels from 1.5 to 2.5 mEq./1., and moderate to severe reactions at levels from 2.0 to 2.5 mEq./1. Fine hand tremor, polyuria, and mild thirst may occur during initial therapy and persist. Transient and mild nausea and general discomfort may also appear during initial therapy. These effects usually subside with continued treatment or temporary reduction or cessation of dosage. If persistent, discontinue dosage. Diarrhea, vomiting, drowsiness, muscular weakness, and lack of coordination may be early signs of toxicity and may occur at levels below 2.0 mEq./1. At higher levels, ataxia, giddiness, tinnitus, blurred vision, and a large output of dilute urine may be seen. Serum levels above 3.0 mEq./1. may produce a complex clinical picture, involving multiple organs and systems. Serum levels should not exceed 2.0 mEq./1. during acute phase.

The following reactions appear to be related to serum lithium levels, including levels within the therapeutic range: **Neuromuscular**—tremor, muscle hyperirritability (fasciculations, twitching, clonic movements of whole limbs), ataxia, choreo-athetotic movements, hyperactive deep tendon reflex; **Central Nervous System**—blackout spells, epileptiform seizures, slurred speech, dizziness, vertigo, incontinence of urine or feces, somnolence, psychomotor retardation, restlessness, confusion, stupor, coma; **Cardiovascular**—cardiac arrhythmia, hypotension, peripheral circulatory collapse; **Gastrointestinal**—anorexia, nausea, vomiting, diarrhea; **Genitourinary**—albuminuria, oliguria, polyuria, glycosuria; **Dermatologic**—drying and thinning of hair, alopecia, anesthesia of skin, chronic folliculitis, exacerbation of psoriasis, xerosis cutis; **Autonomic**—blurred vision, dry mouth; **Thyroid Abnormalities**—euthyroid goiter and/or hypothyroidism (including myxedema) with lower T_3 and T_4. I^{131} uptake may be elevated; rare cases of hyperthyroidism; **EEG Changes**—diffuse slowing, widening of the frequency spectrum, potentiation and disorganization of background rhythm; **EKG Changes**—reversible flattening, isoelectricity or inversion of T-waves; **Miscellaneous**—fatigue, lethargy, transient scotomata, dehydration, weight loss, tendency to sleep.

Reactions unrelated to dosage include: transient EEG and EKG changes, leukocytosis, headache, diffuse nontoxic goiter with or without hypothyroidism, transient hyperglycemia, generalized pruritus with or without rash, cutaneous ulcers, albuminuria, worsening of organic brain syndromes, excessive weight gain, edematous swelling of ankles or wrists, thirst or polyuria, sometimes resembling diabetes insipidus, and metallic taste. A single case of a syndrome resembling Raynaud's has been reported.

How Supplied: 300 mg. capsules in bottles of 100.
300 mg. scored tablets in bottles of 100.

*Individual subscriptions to professional journals are tax-deductible.

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability insomnia associated with anxiety neuroses and transient situational disturbances; an associated with depressive symptoms and as a treatment of symptoms of anxiety if such sy toms are a significant feature of functional or organic disorders, particularly gastrointestina cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by syst atic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucom

Warnings: Not recommended in primary depressive disorders or psychoses. As with all C acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, an diminished tolerance for alcohol and other CNS depressants. ●

Physical and Psychological Dependence: Withdrawal symptoms like those noted with ba turates and alcohol have occurred following abrupt discontinuance of benzodiazep (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Ad tion-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveilla when on benzodiazepines because of their predisposition to habituation and dependei Withdrawal symptoms have also been reported following abrupt discontinuance of benz azepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid o sedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may resu symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and o sional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazep has not been shown of significant benefit in treating gastrointestinal or cardiovascular con nent.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 yea 6mg kg day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum hu therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn w 2 months of first observation. Clinical significance is unknown; but use of lorazepam for longed periods and in geriatric patients requires caution and frequent monitoring for sympt of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depres effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerge rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rab Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastrosch malformed skull and microphthalmia) were seen in drug-treated rabbits without relationsh dosage. Although all these anomalies were not present in the concurrent control group, have been reported to occur randomly in historical controls. At 40mg/kg and higher, there evidence of fetal resorption and increased fetal loss in rabbits which was not seen at l doses. Clinical significance of these findings is not known. However, increased risk of con tal malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam meprobamate) during first trimester of pregnancy has been suggested in several stu Because use of these drugs is rarely a matter of urgency, use of lorazepam during this pe should almost always be avoided. Possibility that a woman of child-bearing potential ma pregnant at institution of therapy should be considered. Advise patients if they become p nant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of loraze and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like c benzodiazepines. As a general rule, nursing should not be undertaken while on a drug s many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and gene disappear on continued medication or on decreasing dose. In a sample of about 3,500 anx patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6. weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, sea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, function disturbance, various gastrointestinal symptoms and autonomic manifestations. dence of sedation and unsteadiness increased with age. Small decreases in blood pres have been noted but are not clinically significant, probably being related to relief of anxiety

Overdosage: In management of overdosage with any drug, bear in mind that multiple ag may have been taken. Manifestations of overdosage include somnolence, confusion and c Induce vomiting and/or undertake gastric lavage followed by general supportive care, mor ing of vital signs and close observation. Hypotension, though unlikely, usually may be contr with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined

Ativan® IV for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase d gradually when needed, giving higher evening dose before increa daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dos may vary from 1 to 10mg/day in divided doses. For elderly or de tated, initially 1-2mg/day; insomnia due to anxiety or transient s tional stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

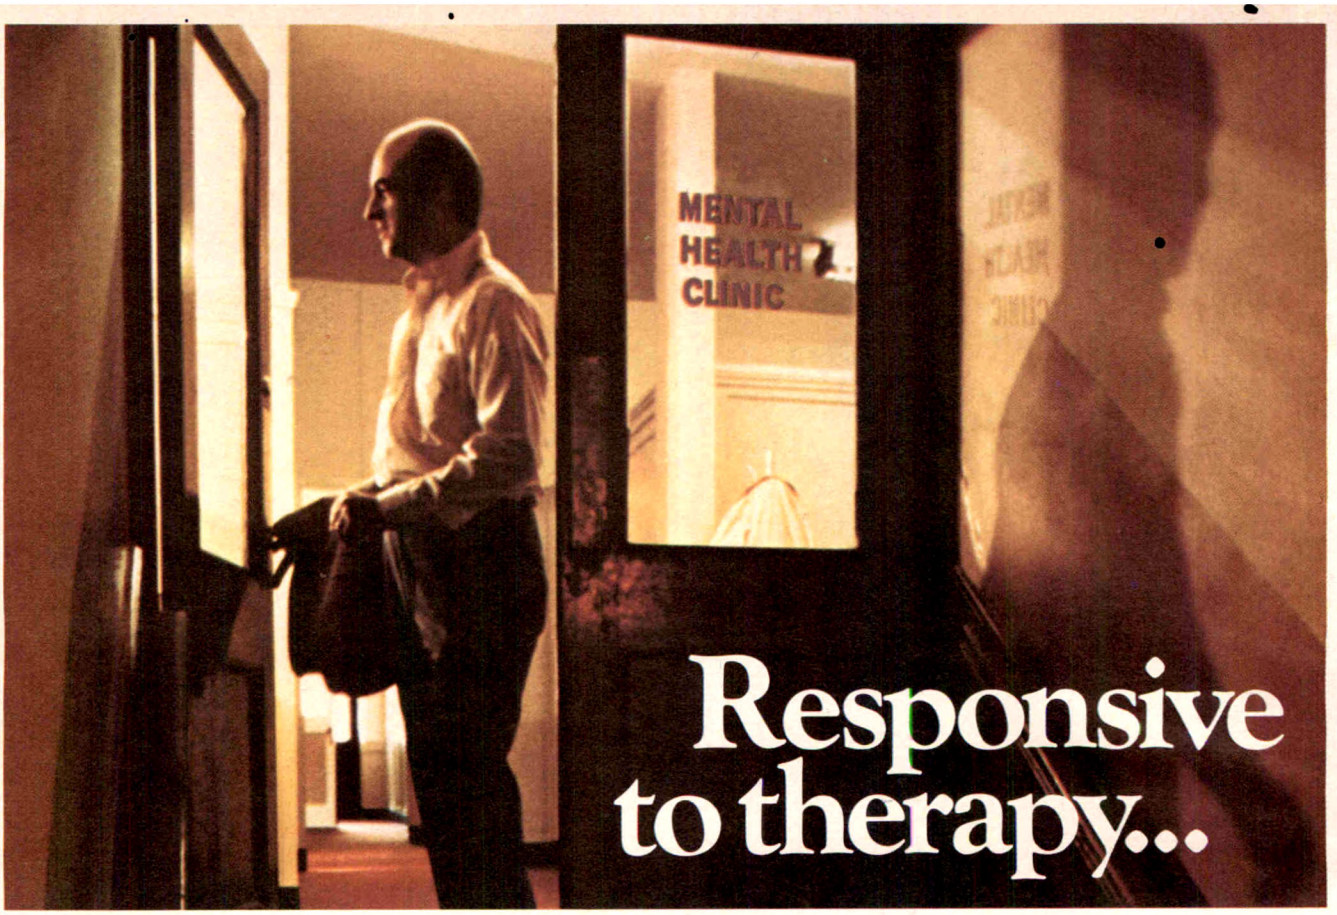
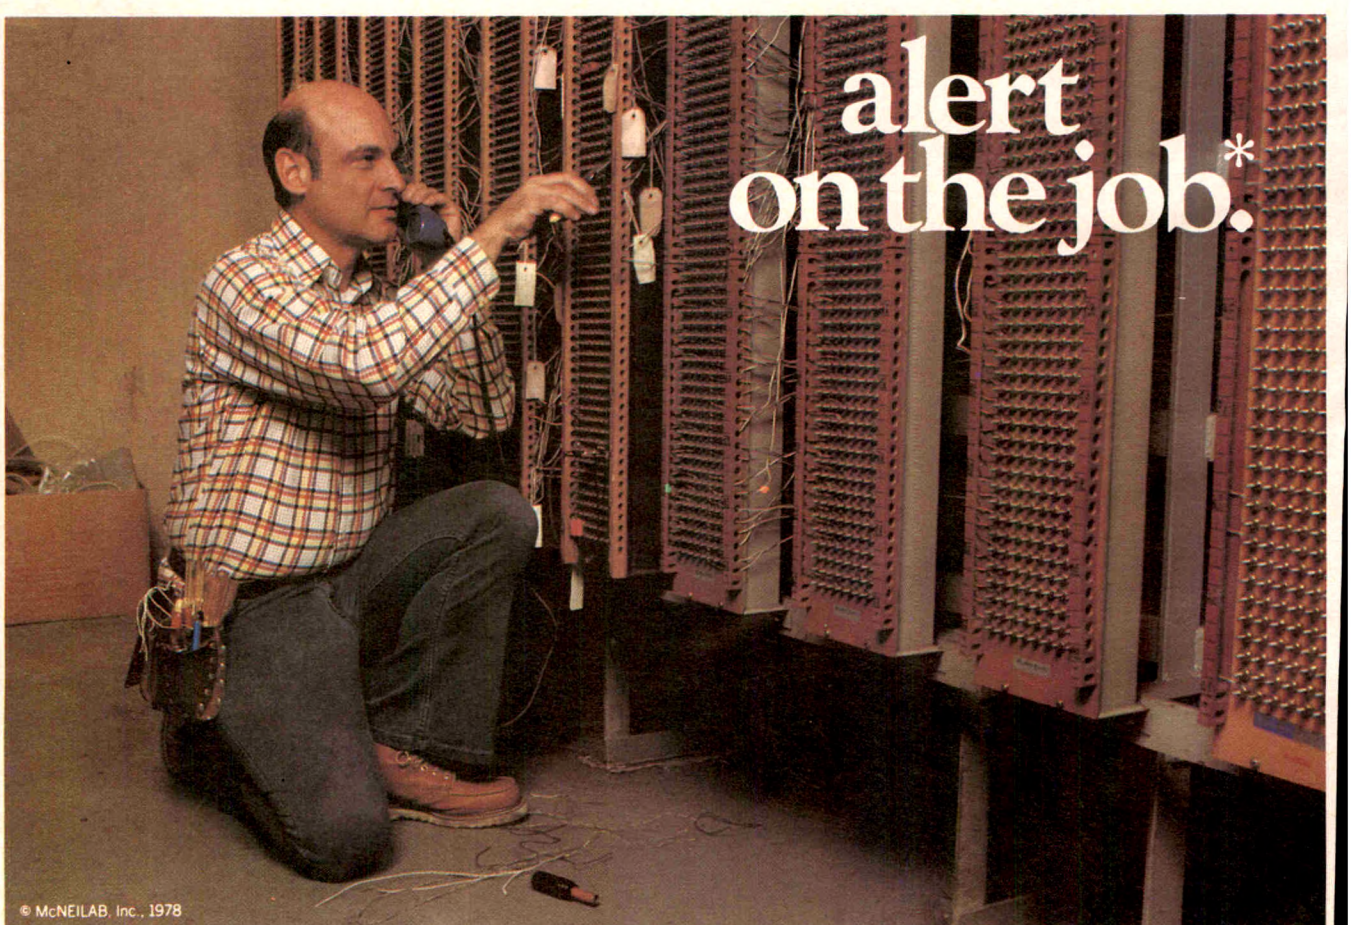
A mixed syndrome. When drug intervention is indicated in patients whose anxiety is accompanied by depressive symptoms, the choice, essentially, is among three basic strategies: (1) an antidepressant; (2) a tranquilizer; (3) a combination of (1) and (2).

With respect to strategy (2), you should know that Ativan (lorazepam) has been shown to be statistically and clinically significantly effective in alleviating the anxiety component of this mixed syndrome, in common protocol controlled studies of 653 patients (337 on Ativan).



Since Ativan was also found to be compatible with tricyclics, if you opt for strategy (3), your patient has the benefit of rapid anxiolytic action, absence of long-acting metabolites and rapid clearance when you decide to discontinue Ativan. All benzodiazepines, however, including Ativan, produce added CNS depressant effects when administered with alcohol and other CNS depressants.



In either case, Ativan offers you the convenience of a b.i.d. schedule and a flexibility not possible with any fixed combination.

See important information on preceding page.

Haldol®
(haloperidol)
tablets/concentrate/injection

For long-term management of psychotic patients... with minimal risk of adverse effects

Highly effective in a wide range of acute and chronic psychotic disorders[1-7]

Permits aggressive titration to effective dosage levels for optimal control[1,4]

Usually leaves patients alert and responsive...
easier to reach with supportive measures[1-3]

Not an actual case history, this situation illustrates the action of HALDOL haloperidol as reported in various clinical studies (available on request).

Minimal risk of hypotension, oversedation, or troublesome anticholinergic effects[3-5,7-9]
Transient hypotension occurs rarely; severe orthostatic hypotension has not been reported. Although some instances of drowsiness have been reported, marked sedation is rare.

Common side effects easily controlled[1,3-7]
Although extrapyramidal symptoms (EPS) have been reported frequently, they are usually dose-related and readily controlled with dose adjustment or antiparkinson drugs. EPS often diminish spontaneously with continued use of HALDOL haloperidol.

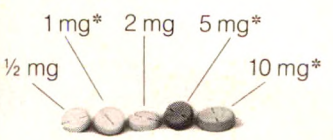
concentrate

A tasteless, odorless, colorless Liquid Concentrate for better patient acceptability: 2 mg per ml haloperidol (as the lactate).



injection

A rapid-acting injection for psychiatric emergencies: 5 mg haloperidol (as the lactate) with 1.8 mg methylparaben and 0.2 mg propylparaben per ml, and lactic acid for pH adjustment to 3.4 ± 0.2.

tablets

5 tablet strengths for convenience in individualizing dosage:

HALDOL® (haloperidol)

*contain FD&C Yellow No. 5 (see Precautions).

tablets/concentrate/injection

A dosage form for every therapeutic need

Summary of Prescribing Information

Contraindications: Severe, toxic CNS depression or comatose states from any cause, hypersensitivity to the drug, Parkinson's disease.

Warnings: ***Usage in Pregnancy:*** Safe use in pregnancy or in women likely to become pregnant has not been established; use only if benefit clearly justifies potential hazards. Infants should not be nursed during drug treatment.

Combined Use With Lithium: Patients receiving lithium plus haloperidol should be monitored closely for early evidence of neurological toxicity.

General: Bronchopneumonia, sometimes fatal, has followed use of major tranquilizers, including haloperidol. Prompt remedial therapy should be instituted if dehydration, hemoconcentration or reduced pulmonary ventilation occurs, especially in the elderly. Decreased serum cholesterol and/or cutaneous and ocular changes have been reported with chemically-related drugs, although not with haloperidol. Mental and/or physical abilities required for hazardous tasks or driving may be impaired. Alcohol should be avoided due to possible additive effects and hypotension.

Precautions: Administer cautiously to patients: (1) with severe cardiovascular disorders, due to the possibility of transient hypotension and/or precipitation of anginal pain (if a vasopressor is required, epinephrine should not be used since HALDOL haloperidol may block its vasopressor activity and paradoxical further lowering of blood pressure may occur); (2) receiving anticonvulsant medication since HALDOL haloperidol may lower the convulsive threshold; (3) with known allergies or a history of allergic reactions to drugs; (4) receiving anticoagulants. Concomitant antiparkinson medication, if required, may have to be continued after HALDOL haloperidol is discontinued because of different excretion rates; if both are discontinued simultaneously, extrapyramidal symptoms may occur. Intraocular pressure may increase when anticholinergic drugs, including antiparkinson drugs, are administered concomitantly with HALDOL haloperidol. When HALDOL haloperidol is used for mania in cyclic disorders, there may be a rapid mood swing to depression. Severe neurotoxicity may occur in patients with thyrotoxicosis receiving antipsychotic medication, including HALDOL haloperidol. FD&C Yellow No. 5 (tartrazine) may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals, especially in those who have aspirin hypersensitivity.

Adverse Reactions: ***CNS Effects:*** *Extrapyramidal Reactions:* Neuromuscular (extrapyramidal) reactions have been reported frequently, often during the first few days of treatment. Generally they involved Parkinson-like symptoms which were usually mild to moderately severe and usually reversible. Other types of neuromuscular reactions (motor restlessness, dystonia, akathisia, hyperreflexia, opisthotonos, oculogyric crises) have been reported far less frequently, but were often more severe. Severe extrapyramidal reactions have been reported at relatively low doses. Generally, extrapyramidal symptoms are dose-related since they occur at relatively high doses and disappear or become less severe when the dose is reduced. Antiparkinson drugs may be required. Persistent extrapyramidal reactions have been reported and the drug may have to be discontinued in such cases.

Withdrawal Emergent Neurological Signs: Abrupt discontinuation of shor term antipsychotic therapy is generally uneventful. However, some patients o maintenance treatment experience transient dyskinetic signs after abru withdrawal. In certain cases these are indistinguishable from "Persistent Ta dive Dyskinesia" except for duration. It is unknown whether gradual wit drawal will reduce the occurrence of these signs, but until further evidence available haloperidol should be gradually withdrawn.

Persistent Tardive Dyskinesia: Although rarely reported with HALDOL halo peridol, tardive dyskinesia may appear during or after long-term therapy. Th risk appears to be greater in elderly patients on high-dose therapy, especiall females. Symptoms are persistent and sometimes appear irreversible; there i no known effective treatment and all antipsychotic agents should be discor tinued. The syndrome may be masked by reinstitution of drug, increasin dosage, or switching to a different antipsychotic agent.

Other CNS Effects: Insomnia, restlessness, anxiety, euphoria, agitatior drowsiness, depression, lethargy, headache, confusion, vertigo, grand m seizures, and exacerbation of psychotic symptoms.

Cardiovascular Effects: Tachycardia and hypotension. ***Hematologi Effects:*** Reports of mild, usually transient leukopenia and leukocytosis, mir mal decreases in red blood cell counts, anemia, or a tendency toward lyr phomonocytosis; agranulocytosis rarely reported and only in association wi other medication. ***Liver Effects:*** Impaired liver function and/or jaundic reported. ***Dermatologic Reactions:*** Maculopapular and acneiform reaction isolated cases of photosensitivity, loss of hair. ***Endocrine Disorders:*** Lact tion, breast engorgement, mastalgia, menstrual irregularities, gynecomasti impotence, increased libido, hyperglycemia and hypoglycemia. ***Gastrointe tinal Effects:*** Anorexia, constipation, diarrhea, hypersalivation, dyspeps nausea and vomiting. ***Autonomic Reactions:*** Dry mouth, blurred vision, u nary retention and diaphoresis. ***Respiratory Effects:*** Laryngospasm, bro chospasm and increased depth of respiration.

The injectable form is intended only for acutely agitated psychotic patier with moderately severe to very severe symptoms.

Caution: Federal law prohibits dispensing without prescription. 0

IMPORTANT: Full directions for use should be read before HALD haloperidol is administered or prescribed.

HALDOL tablets and concentrate (120 ml) are manufactured by McN Laboratories Co., Dorado, PR 00646. ©McN 19

The American Psychiatric Association
Introduces

An essential program for clinicians • learning to incorporate and utilize DSM-III

THE DSM-III INSTITUTIONAL INSTRUCTION KIT

THE DSM-III INSTITUTIONAL INSTRUCTION KIT acquaints physicians and their staff with:

- the multiaxial evaluation method used to report the official DSM-III diagnosis
- the use of new diagnostic categories in making a differential diagnosis
- the use of criteria as guides in making psychiatric diagnosis for the most significant disorders in:

Affective Disorders
Schizophrenia and Related Psychotic Disorders
Anxiety, Dissociative, and Somatoform Disorders
Personality Disorders
Disorders Usually Arising in Childhood or Adolescence

PROGRAM COMPONENTS:
The Instructor's Kit for workshop leaders contains:

- videotape of nine clinical case simulations
- loose-leaf binder containing:
  - — 4 audiocassettes plus transcripts of original faculty presentations
  - — 39 slides complementing audiotaped presentations
  - — course syllabus, patient histories, worksheets, references
  - — DSM-III diagnosis for each of 30 patient histories

The Participant's Kit for individual workshop members includes:

- course syllabus
- patient histories
- worksheets

CONTINUING MEDICAL EDUCATION (CME) CREDIT:
These learning materials can be used by educational organizations or institutions in the development of, or as an adjunct to, a variety of learning programs for CME Category 1, 2, or 5.

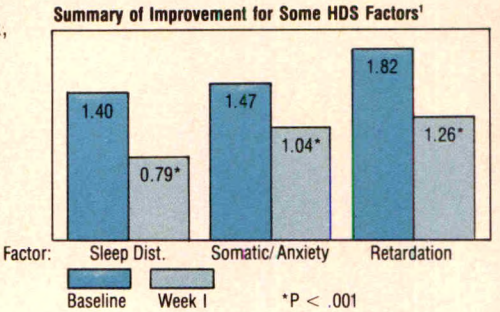
When depressive symptoms come in a cluster of blues...



Adapin® (doxepin HCl) helps patients see life in all its colors

Improvements noted at one week

Depressed patients often present with fatigue, anorexia, anxiety, mood swings, loss of interest, *and most frequently, early awakening and insomnia*. In a summation of 9 clinical studies involving 198 patients, significant clinical improvement was noted after the first week of doxepin treatment.[1] However, optimal antidepressant response may not be evident for two to three weeks.

Summary of Improvement for Some HDS Factors[1]

Normalized sleep patterns

In a study of clinically depressed patients with symptoms of insomnia, treatment with doxepin significantly reduced difficulty falling asleep, difficulty staying asleep and frequency of early morning awakening.[2]

Low potential for cardiotoxicity

The incidence of tachycardia and hypotension, which have been observed during treatment with tricyclic antidepressants, has been reported infrequently with doxepin. In 452 patients given doxepin, the incidence of tachycardia was 2.88%; in 495 patients, the incidence of hypotension was 2.62%.[3]

Now available... 75 mg capsules for h.s. dosage

Brief Summary of Prescribing Information ADAPIN® (doxepin HCl) Capsules

Indications–Relief of symptoms of anxiety and depression.

Contraindications–Glaucoma, tendency toward urinary retention or hypersensitivity to doxepin.

Warnings–Adapin has not been evaluated for safety in pregnancy. No evidence of harm to the animal fetus has been shown in reproductive studies. There are no data concerning secretion in human milk, nor on effect in nursing infants.

Usage in children under 12 years of age is not recommended. MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug, as serious side-effects and death have been reported with the concomitant use of certain drugs and MAO inhibitors.

In patients who may use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage.

Precautions–Drowsiness may occur and patients should be cautioned against driving a motor vehicle or operating hazardous machinery.

Since suicide is an inherent risk in depressed patients they should be closely supervised while receiving treatment.

Although Adapin has shown effective tranquilizing activity, the possibility of activating or unmasking latent psychotic symptoms should be kept in mind.

This product contains FD&C Yellow No. 5 (tartrazine) which may cause allergic-type reactions (including bronchial asthma) in certain susceptible individuals. Although the overall incidence of FD&C Yellow No. 5 (tartrazine) sensitivity in the general population is low, it is frequently seen in patients who also have aspirin hypersensitivity.

Adverse Reactions–Dry mouth, blurred vision and constipation have been reported. Drowsiness has also been observed.

Adverse effects occurring infrequently include extrapyramidal symptoms, gastrointestinal reactions, secretory effects such as sweating, tachycardia and hypotension. Weakness, dizziness, fatigue, weight gain, edema, paresthesias, flushing, chills, tinnitus, photophobia, decreased libido, rash and pruritus may also occur.

Dosage and Administration–In mild to moderate anxiety and/or depression: 25 mg t.i.d. Increase or decrease the dosage according to individual response. Daily dosage, up to 150 mg may be taken at bedtime without loss of effectiveness. Usual optimum daily dosage is 75 mg to 150 mg per day not to exceed 300 mg per day.

Antianxiety effect usually precedes the antidepressant effect by two or three weeks.

How Supplied–Each capsule contains doxepin, as the hydrochloride. 10 mg, 25 mg, 50 mg, 75 mg and 100 mg capsules in bottles of 100 and 1000.

For complete prescribing information please see package insert or PDR.

Adapin® (doxepin HCl) ... effective single-entity drug with antidepressant and antianxiety effects

A-252

THE 48-HOUR
LOXITANE®
Loxapine Succinate
EFFECT...
Prompt
symptom
improvement

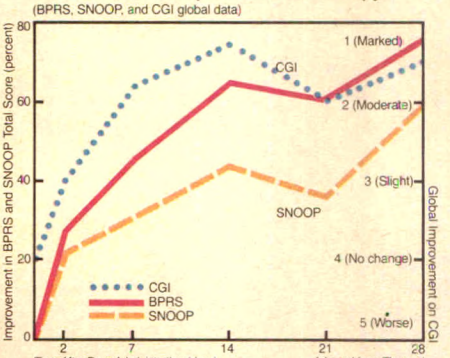
...y response—the first step ard early resocialization

...a relatively short time on LOXITANE® ...ipine Succinate, hospitalized ...zophrenic patients usually become ...er to reach, easier to manage, more ...ciable, and cooperative. A series of ...linical studies[1-4] shows an impressive decrease in conceptual disorganization, thinking disorder, hallucinatory behavior and anxiety-depression during the first 48 hours.

The results in one group of 17 young adult schizophrenics treated at a university hospital typify general clinical experience. In the first 48 hours, these patients achieved a mean overall symptomatic improvement of more than 20% in BPRS.[1] (See chart)

Continued overall improvement... helps facilitate a return to more normal activities

Near maximal control was reported by week four; many behavior patterns approached normal. In other studies, a mean overall improvement of almost 80% was seen by 28 days.[2,3] Prompt therapeutic response and steady progress can help strengthen the patient's capacity to cope with daily living and relationships.



...Minimal risk of certain toxicities... encourages compliance.

On LOXITANE, physical health is rarely compromised by certain toxicities. Renal, hematopoietic, cardiotoxicity, phototoxicity and photosensitivity have not been reported to date.* Therapy in most cases is not interrupted by intolerable side effects. Sexual side effects have not been a significant problem; anticholinergic effects are usually mild, and extrapyramidal reactions are generally easily controlled. Well-tolerated LOXITANE means less frequent need to interrupt therapy—fewer problems with patient compliance.

Note: LOXITANE, as with certain other neuroleptics, lowers the convulsive threshold and should be used with extreme caution in patients with a history of convulsive disorders.

*Although not reported to date, the possibility of phototoxicity, cardiac, renal, or blood toxicity cannot be ruled out at this time. Transient liver enzyme changes not definitely related to LOXITANE have been reported.

Recommended Daily Dosage

Dosage	Initially: 20-50 mg During first 24 hours: up to 100 mg Usual therapeutic level: 150 mg/day Maintenance: 60-100 mg/day Maximum: 250 mg/day Dosage may be divided as necessary. Reduced dosage in geriatrics and adolescents should be considered.

Brief Summary
LOXITANE® Loxapine Succinate Capsules
LOXITANE® C Loxapine Hydrochloride Oral Concentrate
LOXITANE® IM Loxapine Hydrochloride

INDICATIONS: Manifestations of schizophrenia.
CONTRAINDICATIONS: Comatose or severely depressed states; hypersensitivity to the drug.
WARNINGS: Safe use during pregnancy or lactation has not been established; weigh potential benefits against possible hazards. Not recommended for use in children under 16. May impair mental and/or physical abilities especially during early therapy; warn ambulatory patients about activities requiring alertness and concomitant use of alcohol or other CNS depressants. Not recommended for management of behavioral complications in mentally retarded patients.
PRECAUTIONS: Use with extreme caution in patients with a history of convulsive disorders; use with caution in patients with cardiovascular disease or in those with glaucoma or a tendency to urinary retention particularly when on concomitant anticholinergic medication. Loxapine has an antiemetic effect in animals which might occur in man masking signs of overdosage of toxic drugs and obscuring intestinal obstruction or brain tumor. Since possible ocular toxicity cannot be excluded, observe carefully for pigmentary retinopathy and lenticular pigmentation. Slightly higher incidence of extrapyramidal effects possible following IM administration.
ADVERSE REACTIONS: *CNS effects,* other than extrapyramidal, infrequent. Mild drowsiness may occur at beginning of therapy or upon dosage increase, usually subsides with continued therapy. Sedation, dizziness, faintness, staggering gait, muscle twitching, weakness and confusional states have been reported. Extrapyramidal reactions often occur early in treatment, manifested by Parkinson-like symptoms (tremor, rigidity, excessive salivation, masked facies, akathisia); controllable by dosage reduction or antiparkinson drugs at usual dosages. Dystonic and dyskinetic reactions, while less frequently occurring, may be more severe, requiring dosage reduction or temporary withdrawal plus appropriate counteractive drugs. *Persistent Tardive Dyskinesia* may appear during prolonged therapy or following discontinuance, the risk greater in the elderly, especially females, on high dosage. Symptoms, persistent and in some patients apparently irreversible, are characterized by rhythmical involuntary movement of the tongue, face, mouth and jaw sometimes accompanied by involuntary movement of extremities. Since there is no known effective treatment, discontinue all antipsychotic drugs if symptoms appear. Reinstitution of treatment, increased dosage or switching to another agent may mask syndrome. The syndrome may not develop if medication is stopped when fine vermicular movements of the tongue first appear. *Cardiovascular Effects:* Tachycardia, hypotension, hypertension, lightheadedness and syncope. ECG changes, not known to be related to loxapine use have been reported. *Skin:* Dermatitis, edema of face, pruritus, seborrhea. Possible photosensitivity and/or phototoxicity; skin rashes of unknown etiology seen in a few patients in hot summer months. *Anticholinergic:* Dry mouth, nasal congestion, constipation, blurred vision (more likely to occur with concomitant use of antiparkinson agents). *Other:* Nausea, vomiting, weight gain or loss, dyspnea, ptosis, hyperpyrexia, flushed facies, headache, paresthesia, polydipsia. Rarely, galactorrhea and menstrual irregularity of unknown etiology.

Lederle
LEDERLE LABORATORIES
A Division of American Cyanamid Company
Wayne, New Jersey 07470

222-0 ©1979

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

Dosage: Dosage must be individualized according to the degree of mental and emotional disturbance, and the smallest effective dosage should be determined for each patient.

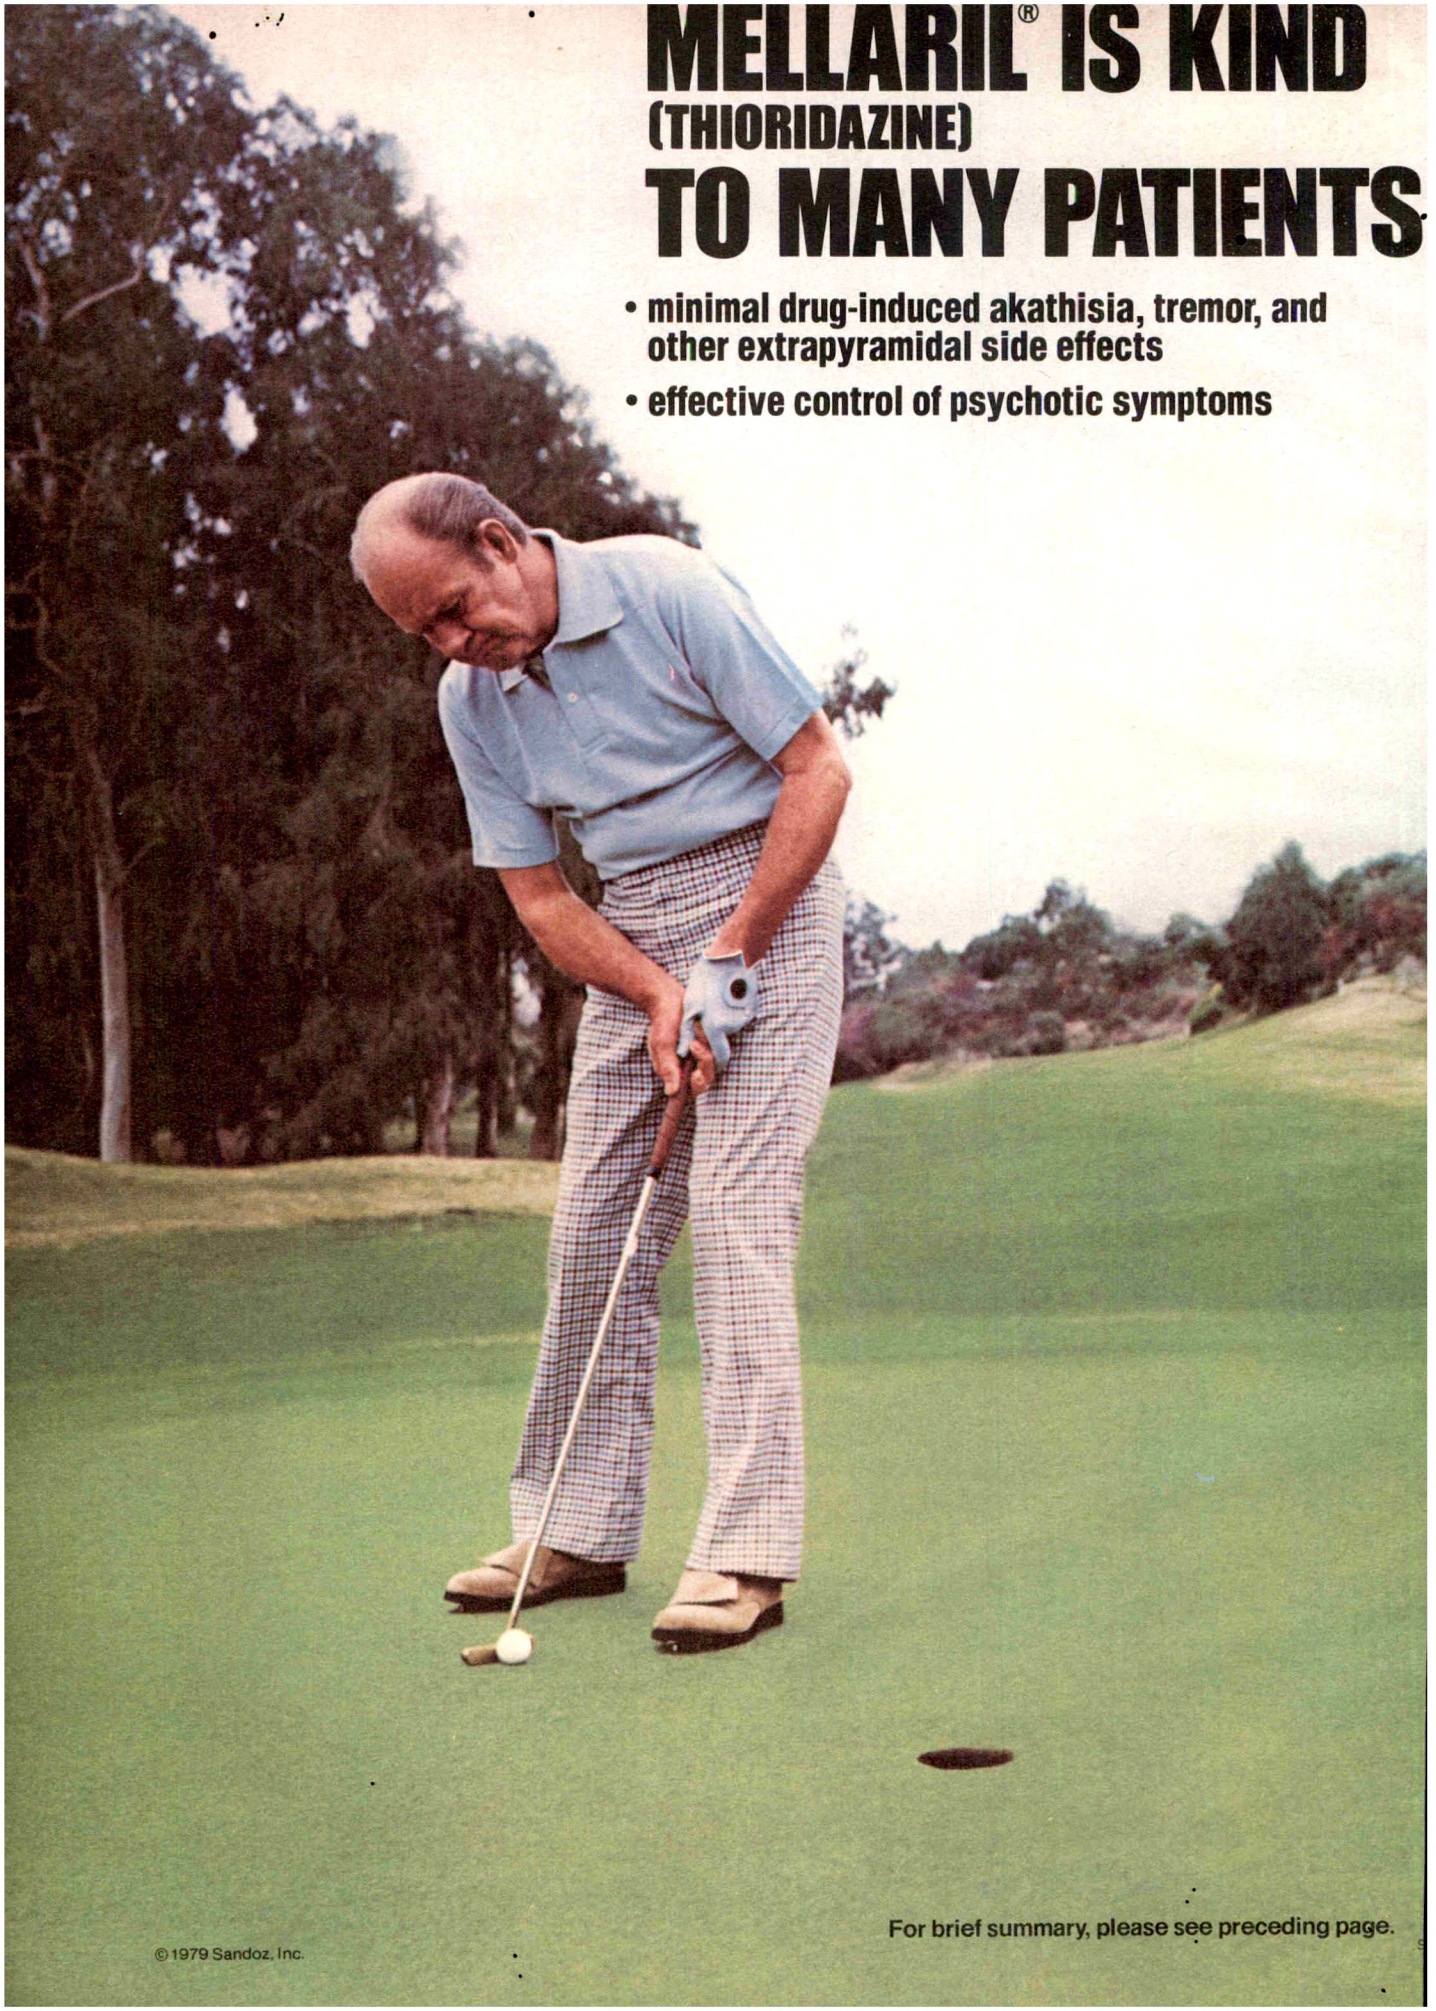
MELLARIL® IS KIND (THIORIDAZINE) TO MANY PATIENTS

- **minimal drug-induced akathisia, tremor, and other extrapyramidal side effects**
- **effective control of psychotic symptoms**



Mellaril® (thioridazine) is kind *two* ways to the patient with psychotic symptoms. It has an impressive record of relieving agitation, excitement, and hallucinations, while successfully helping the patient live and perform in the community. And, unlike other major tranquilizers, Mellaril (thioridazine) causes minimal akathisia or other extrapyramidal symptoms. Mellaril (thioridazine) is contraindicated in patients with hypertensive or hypotensive heart disease of extreme degree.

Effectiveness plus infrequent side effects—that's the kind of kindness the physician likes to see in a major tranquilizer!

MELLARIL® (THIORIDAZINE)

TABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, USP

MELLARIL-S™ (thioridazine) SUSPENSION, per 5 ml (teaspoon): thioridazine base equivalent to 100 mg thioridazine HCl, USP

MELLARIL® IS KIND
(THIORIDAZINE)
TO MANY PATIENTS
• minimal drug-induced akathisia, tremor, and other extrapyramidal side effects
• effective control of psychotic symptoms
For brief summary, please see preceding page.

Pathological Grief and the Activation of Latent Self-Images

BY MARDI J. HOROWITZ, M.D., NANCY WILNER, CHARLES MARMAR, M.D., AND JANICE KRUPNICK, M.S.W.

The authors studied the case material for patients treated with either psychoanalysis or brief therapy to examine the basis for the various states of pathological grief after bereavement. They view these states as intensifications or unusual prolongations of states found in normal grief and describe them in terms of the reemergence of self-images and role relationship models that had been held in check by the existence of the deceased person. This conclusion concerning preexisting mental schemata leads to an elaboration and partial revision of theories of regression, ambivalence, and introjection as causes of pathological grief.

For some people, mourning the loss of a loved one involves a process so unbearably painful, protracted, or tenaciously blocked that it can be described as pathological grief. Freud (1) and Abraham (2) attributed such states to preexisting ambivalence toward the deceased, followed after the death by internalization of the other and aggression directed toward the self. They described this process as leading to feelings of self-hatred and deflation of self-esteem. In this paper, we will elaborate on these alterations of the self-image in pathological grief. Our intention is not to present a comprehensive explanation of a multidetermined phenomenon but to focus on one process: the review of self-images and role relationship models initiated by a loss.

Presented at the 131st annual meeting of the American Psychiatric Association, Atlanta, Ga., May 8–12, 1978. Received May 24, 1978; revised Feb. 16, 1979, July 30, 1979; accepted Sept. 24, 1979.

DEFINITIONS

The terms "grief" and "mourning" have been used in many ways. In this discussion, "grief" refers to phenomena of subjective experience and behavior that occur after psychological recognition of a loss. "Mourning" refers to processes in which states of grief are eventually attenuated as the person recognizes and adapts to loss.

"Pathological grief" is the intensification of grief to the level where the person is overwhelmed, resorts to maladaptive behavior, or remains interminably in the state of grief without progression of the mourning process toward completion. "Pathological mourning" involves processes that do not move progressively toward assimilation or accommodation but, instead, lead to stereotyped repetitions or extensive interruptions of healing.

EARLY PSYCHOANALYTIC VIEWS

In a series of papers, Abraham (2, 3) and Freud (1) differentiated normal from pathological grief. Normal grief was characterized by painful dejection, loss of interest, and inhibition of activities. Pathological grief reactions included additional features, such as episodes of panic, hostility toward the self, regression to narcissistic self-preoccupation, and other signs of deflated self-esteem.

The explanation for these supplemental features of pathological grief included several components of pathological mourning. A preexistent ambivalent rela-

tionship with the deceased led to self-hatred after the loss because of internalization of attributes of the lost object into the ego and super ego. Aggressive drives, now directed toward the self, led to self-blame, self-hate, and self-disgust.

This early work indicated the typical signs of pathology, the gradient between mourning and melancholia, the importance of the quality of the previous relationship, and the serious consequences of ambivalence.

Perhaps because of their pioneering nature, the works of Abraham and Freud suggested an excessive cleavage between normal and pathological grief. Subsequent field studies of bereavement experienced by nonpatient as well as patient populations indicate that hostility toward the self, exemplified as pathogenic by Abraham and Freud, is not uncommon in typical grief reactions of relatively random populations (4–8). States of inertia, hypochondriasis, numbness, and apathy have also been noted; these too may not be so unusual, intense, out of control, or prolonged as to be called pathological. Various normal and depressive states of mind were further clarified during the period when the theory of ego psychology was developed.

EGO PSYCHOLOGY OF DEPRESSIVE STATES

A state of sadness accompanied by dejection, loss of interest, and relative reduction of social activities has long been regarded as normal grief and does not merit a diagnosis of pathological grief or any other depressive syndrome. Depressive states take other and varied forms. In one state the person feels frighteningly sad, alone, and needy. In another, instead of feeling bereft and helpless he feels strongly hostile toward himself and others. In still another fairly distinct ego state, the person has feelings that are not so much those of fear or anger as they are feelings of despair, worthlessness, and defectiveness (9, 10). To these states of panic, rage, and deflated self-esteem Jacobson (11) and Schmale and Engel (12) added a fourth, which is much less intense in emotional tone and more hibernative or energy-conserving. This state is characterized by withdrawal and vague sensations of numbness, emptiness, and hypochondriacal concerns.

These depressive states have been explained according to object relations and cognitive-psychodynamic points of view. Internalization of early strained interpersonal relationships may leave a residue of self- and object representations conducive to depression when there is a regressive return to these forms precipitated by the stress of loss (13–15). Incomplete early separation from the mothering figure may render a person especially prone to such regressions in later life (16).

Not in conflict with such formulations but emphasizing an information-processing point of view, Bibring (17) suggested that entry into these different depressive states might be the consequence of particular cognitions, a concept recently elaborated on by Seligman (18) and Beck (19). They observed that the states of agitated sadness and panicky helplessness were initiated by a train of thought that moved from seeing oneself as strong and competent to seeing oneself as weak and helpless. The rage states—anger directed both outward and toward the self—were seen as shifts in conceptualization from the self as good to the self as evil. The states of self-disgust were the result of an alteration in the sense of self from lovable to unworthy or inferior.

Bereavement could initiate these trains of thought about the meaning of the loss of a relationship or the failure to prevent that loss. These implications can shift the sense of self from that of being strong, concerned, and worthwhile to self-images of being weak, incompetent, and uncaring. The various depressive states could be viewed as the results of experiencing such thoughts consciously or unconsciously.

Four depressive states have been described and can be labeled by predominant emotional tone: fear, rage, shame, and hibernation. All of these states occur in normal grief and do not warrant diagnoses. Pathological grief, as already mentioned, is the intensification of such states to a level where the person feels overwhelmed and either resorts to maladaptive behavior or remains interminably in that state. We studied the psychodynamics of people with pathological grief to understand why such intensification or prolongation occurs.

METHOD OF CLINICAL INVESTIGATION

Material for study was available from two contexts. One involved the use of process notes from the psychoanalyses of 3 adults with character neuroses. The patients were 2 women and 1 man who mourned the death of a parent while in treatment, although the loss had occurred years before, during critical developmental periods. The second context was time-limited (12 sessions) brief psychoanalytically oriented therapy of adults with symptoms at the neurotic level after the recent death of someone close to them.

The latter context included systematic evaluations before and after therapy, with audio and video recordings and transcriptions of many of the therapy and evaluation hours. This material was collected after written informed consent was secured from more than 50 subjects participating in a program of clinical research and therapy. Review of the case material for about 25 of these patients led to the present report. Virtually all of the patients were white, middle-class, West Coast Americans with at least a high school education. A little less than three-quarters of the patients were women; the majority of the entire group were between 20 and 40 years of age.

CONFIGURATIONAL ANALYSIS

Detailed case review by configurational analysis evolved from the kind of formulations made during psychodynamically oriented case conferences in major training centers. It consists of 10 systematic steps with related formats, described elsewhere in detail (20). Materials included case summaries, process notes, video and audio recordings when available, and transcripts of selected interviews. The initial descriptions of the problems are amplified first by a focus on observable, reportable experience and behavior as elaborated by analysis of the states the patient is experiencing. Then the self-image and role relationship themes that characterize important recurrent states are modeled through an analysis of the content of each state. These themes, usually expressed as dyadic or triadic structures, are traced through the person's developmental history, the immediate course of entry into problem states, and the period of change that may occur during and after psychotherapy. This is followed by formulation of the person's major active constellations of conflicted aims, ideas, and emotions. The related controls, defenses, and styles of information processing are included.

The problem states of these bereaved patients conformed well to the patterns of pathological grief described above. There were patients whose main complaints could be described as a frighteningly sad response to loss, those who experienced feelings of out-of-control rage after loss, and those who had a deflated or hibernative response to loss. Although each patient might identify one such state as a major problem, several problem states were manifest in all of them. Patients varied in their response to experiencing similar states; in some states they felt more out of control, vulnerable to impulsive action, or distressed than in others. They were able to work their way out of one state and into another with various levels of ease or difficulty. Although all of the patients had the same set of states, they differed in terms of which states were pathological or caused the most problems.

What seemed pathological was not the emotional or ideational content of a state but its intensity or prolongation. An experience that was too intense and therefore pathological was one that crossed the person's usual threshold of tolerance. It was not merely painful but too painful; it was not just threatening but too threatening.

The states themselves were seldom new varieties of experience, although the current episode was often more intense or protracted than previous episodes. Patients could remember times before the loss when they had had shorter and less intense periods of panic, self-hatred, deflation, or hibernation. Infrequently, a new state emerged that the patient did not remember experiencing before the loss. In such instances the state tended to be a repetition of an experience that had emerged for the first time during the loss itself. Examples of such new states might include the recurrence of a depersonalized dazed state that had accompanied initial recognition of the death, a hyperalert excitation after viewing a traumatic sight, or a personal repetition of experiences of the deceased that the patient had observed before the death occurred.

SELF-IMAGES AND ROLE RELATIONSHIP MODELS

Certain self-images and role relationship models predominate in each state; we infer that these are organizing principles which are partly responsible for the repetition of a given state over time. We will describe these models of self and others in sequence. Our observations confirm earlier impressions and add little that is not contained in the clinical literature. What expands the literature is an attempt to clarify the process of reversion to preexistent self-images.

The essential point is that recent internalization of ambivalent attitudes toward attributes of the lost person is not the major reason for states of pathological grief. Although these new identifications and attitude formations are important processes, a major cause of pathological grief appears to be the reemergence of earlier self-images and role relationship models. These were established before the loss but were held in check by a more positive relationship.

News of the loss activates these usually dormant organizers of mental life; it instigates thought processes aimed at examining the implications of the news. Inner models are revised so that they conform to new realities. This involves a completion tendency that leads to repetitive and sometimes intrusive thinking (8). In the course of such ideation, there is review of the current primary model of attachment to the lost person as well as to all other models of attachment (21). Latent self-images and role relationships that are usually unconscious are actively contemplated, whether awake or dreaming, by primary and secondary process modes of review (22).

When there is activation of previously conflicted, troublesome, dissociated role relationship models, the process evokes unusually intense negative effects. Defenses are instigated as a feedback process to reduce pain and threat, with possible interruption of the working-through process. Persistent tendencies to repetition produce intrusive episodes; excessive defenses produce experiences of numbness and avoidance. This combination results in unusually intense and protracted states.

In our sample of patients we found that troublesome preexistent self-images and role relationship models were common precursors to pathological grief. Before reviewing them, we will discuss a model of normal mourning for purposes of comparison.

NORMAL MOURNING

Normal mourning is a theoretical construct, a statement about routes to a hypothetical and ideal acceptance of separation. In this prototype the relationship with the deceased was one in which both self and other were regarded as competent, giving, caring, and responsible. Before the loss this role relationship model fostered states of mutuality and contentment.

In normal mourning the representations remain realistic after the loss. The self is experienced as bereaved but competent to tolerate sadness, and the other is experienced as lost but remembered. The interaction is one of pining, preoccupation, and symbolic search for repair (23). Gradual acceptance of the lost attachment as part of the past, as no longer present, or as part of the future (except in some new form) attenuates the state of sadness, pining, and preoccupation. During the initial period of intense sadness, emptiness, and fear of being alone, the experience is made tolerable by support from others and through intermittent periods of calm achieved by moderate use of denial.

In reality, in addition to the ideal resolution described above, mourning usually includes transition through other states, such as fear, rage, and deflation. The difference between normal and pathological grief is that in normal grief the transition—however painful—is not overwhelming, interminable, or prematurely interrupted. Instead, each model of attachment is reviewed and ties are detached in terms of expectancy for the future. Competent self-images and readiness for a new attachment are stabilized. Personal suffering is accepted, and the lost attachment is retained in the present as a rewarding memory.

PREDISPOSITION TO FRIGHTENINGLY SAD RESPONSE TO LOSS

Reports by clinicians about people who are predisposed to a frighteningly sad response to loss define the preexistent role relationship as one of dependency and orality (24). That is, the person is seen as having relied on the strong, caring other for nurturance. With loss of the other, the person remains dependent and the need becomes frightening. The most frequent self-image in these states is that of a weak, abandoned, and needy waif in desperate hope of rescue, with intense fear that such rescue will not occur. On closer study, however, additional impressions are gained. The preexistent relationship was often one in which both the self and the other were conceptualized as strong; representations of the self as weak were held in check by these people.

The person predisposed to overwhelming, frighteningly sad states had several role relationship models. In two of these role relationship models, the self was weak, either in relation to a strong nurturing other or to an abandoning or lost other. To submerge this traumatic view of the needy self abandoned by a caretaker, the patient developed a role relationship model in which the other served not only as supplier but as stabilizer of the strength of the self. With recognition of the death, the patient was forced to once again contemplate his vulnerability (16, 25).

The patient's self-image shifted back, from that of a strong person well sustained by the relationship with a strong other to the preexistent structure of a weak, helpless waif supplicating in vain for rescue by a lost or abandoning person. The state associated with this role relationship model was more than sad yearning; it was an agitated, desperate, and intolerable sadness that led to insistent demands for help. If help seemed unavailable, there was transition to a state of dullness and defeat (12).

The preexistent self-image as a weak, helpless waif was the structural basis for what Seligman (18) termed "learned helplessness" and Beck (26) referred to as "depressogenic schemata and premises." The developmental precursors in separation and attachment have been well reviewed by Bibring (17), Bowlby (21), and Rubenfine (27).

After the loss of an important relationship, any person will feel frightened and sad as he experiences yearning that cannot be fulfilled. Any person will have a shift to needy, helpless self-images, but these self-images may be less desperate in quality, less discrepant with other self-images, and less compelling as organizers of information than the needy self-images of a person with conflicts or developmental defects in this area. Most people are more readily able to complete a review of the situation, estimate the degree of helplessness, and consequently experience restoration of morale. Competent self-images may become more stable without as much reliance on another person to maintain a view of the self as strong. The predisposed person who has more peremptory self-images as weak and helpless will review the implications of the loss more intensely and will not as readily shift back to a competent self-image.

Of course, other factors, such as fear of sadness and of feeling too weak to tolerate mourning, contribute to the panic of such frighteningly sad states. However, the interrelationship of self-images and role relationships with these other aspects of mental process is beyond the scope of this paper.

RAGE STATES AND DEFLATED STATES

Any attack on the integrity of the self evokes a hostile response. One response to the loss of a relationship is to experience it as an attack on the self with rage at the source of the attack. The attacker can be posited to be the self, the deceased, others involved in the death, or the agents of destiny. People exempted

from the loss may be hated because they do not have to experience the burdens of this fate.

Among the patients whose rage states became a problem in the material we reviewed, the most common images were oscillations between the self as a betrayed needy person and the self as an evil, greedily consuming, destructive person. These self-images were developed long before the loss. They had been held in check by development and stabilization of images of the self as kind and good. This stabilization occurred because the relationship before the loss was construed as between people who were kind and good to each other. The deceased protected the self from evil, in effect, because exchanges of a loving nature maintained a state of mutuality.

In one version of the implications of the separation, the deceased was seen as an evil deserter who willfully betrayed the needy self. This injury led to states of explosive rage, with hostility diffusely expressed toward anyone within range as well as toward the deceased. Role reversal was also very common. With recognition of the rage, the self became the one who was evil, a destroyer of the deceased, who was now cast as victim. This led to states of guilt, remorse, and self-loathing, with a fearful expectancy of accusation or punishment.

Oscillation or reversal of these role models led to shifts between anger and guilt. These shifts in state resulted from an undoing defense aimed at reducing the intensity of either affect. Although this served defensive purposes (28), there were times when transitions to impulsively self-destructive states of mind occurred. Suicidal acts were products not only of self-hatred and self-punishing states but also of despair over weakness, loss of coherence of the self, ideas of merger with the victim, and wishes for retribution from others (by making them mourn the lost self) (29).

The patients who developed excessively intense or prolonged deflated states had preexisting tendencies to self-images as worthless, defective, or disgusting. A relevant relationship model was one between a scornful superior critic and a contemptible, worthless person. As with most role relationship models, the self could be placed in either position.

The relationship before the death had components of admiration and appreciation that stabilized a worthwhile self-image. Loss of the relationship altered this stability and a worthless self-image emerged, organizing experienced thought and emotion. A worthless self-image was also evoked when the self was blamed for being unable to prevent the loss or felt scorned by the other. The idea of having been left because of defects of the self led to feelings of deflation, shame, and dejection accompanied by withdrawal. In an additional defensive shift, there was movement from such relationship views to illusions of self-sufficiency. As is common in such insulation, no joy and little pain was felt; the patient was blank, deadened, and numb (30).

The loss of admiration and appreciation was not limited to loss of a real, present situation. It involved loss of a projected future. For example, in some instances the deceased had been approving in the past but had devalued the patient more recently. The patient then cherished a belief that approval would be restored in the future. Death destroyed that projection, and the patient shifted to worthless self-images.

INTERNALIZATION: SELF WHERE OTHER WAS

If a person fantasizes restoration of the lost other and gradually surrenders these fantasies as unrealistic, a form of learning may take place in which he revises his models. The self may become like the other. At first, whole aspects and traits of the other may be mimicked to gain essential parts. Then, by conscious contemplation, the person may synthesize the important elements of what was lost, so that they are valued and sought in future relationships (31).

For example, the person may no longer expect that the function served by the deceased will automatically be served by new attachments. He learns to fulfill both roles of the lost relationship, to be the strength for others who might otherwise be weak, the good for others who might otherwise be evil, the appreciator for those who might otherwise feel worthless. Such processes lead to the mellowing of interpersonal relationships, which is a positive consequence of grief.

DRIVES AND COGNITIVE PROCESSING

We have paid little attention to drive theories, which are prominent in the pychoanalytic literature on this topic. Briefly, drives can be expressed in derivative forms as responsible for the activation of particular role relationship models and for the intensity of related aims (8, 32, 33). Libidinal or aggressive drive development, as predisposition, can be described in terms of relationship models that have been well established and the priority they have been given. Fixation can be discussed in terms of capacity, readiness, or lack of readiness to give up a specific role relationship model even when retention of the model involves loss of reality-based thinking.

Beck and Kovacs (19, 26, 34–36) have been prominent observers and theorists of cognitive processes in depressed people. For example, premises such as "If I am not loved I cannot go on living" have been seen as ideas that anchor a person to a depressive state. Our experience with the patients whose case material we reviewed supports Beck's assertions of the importance of the cognitive processes of devaluation of the self, the exaggeration of impediments to contented living, and viewing of the future as hopeless. The self-images and role relationship models de-

scribed here are conceptualized as the usually unconscious formats of meaning that influence the organization of such thoughts. Kovacs and Beck (36) have been developing the same view with their concept of depressogenic schemata.

SUMMARY

We have described several states that constitute pathological grief when they are excessively intense or prolonged, together with the prototypical self-images and role relationship models that organize each state of mind. Early traumatic experiences, such as parental loss during childhood, or other developmental strains result in unusual salience of such models during adult life, even when compensatory relationships have developed and more competent self-images have been stabilized.

The compensatory relationship, when present in reality or fantasy, stabilizes the advanced structures and promotes active, harmonious mental states. When such relationships are lost, a person reviews his repertoire of self-images and role relationship models. Many bereaved people experience transient states of frightening sadness caused by weakened views of the self; many experience states of hatred and of deflation arising from evil or worthless self-images. Those predisposed to pathological grief cannot readily complete review of such self-images and relationship models; instead, the state during the review becomes unusually intense and interminable or excessive controls prevent review of activated role relationship models, so that mourning is never completed.

Tardive Dyskinesia: Summary of a Task Force Report of the American Psychiatric Association

BY THE TASK FORCE ON LATE NEUROLOGICAL EFFECTS OF ANTIPSYCHOTIC DRUGS

Abnormal movements associated with the prolonged use of antipsychotic drugs (tardive dyskinesia) occur in at least 10%–20% of the patients at risk; prevalence is higher among the elderly. The cause is unknown, but increased sensitivity to dopamine in the basal ganglia may contribute to the pathophysiology. Many treatments have been evaluated; none is satisfactory. While the problem is serious, an alarmist view is unwarranted, especially since many cases are detected early and improve spontaneously. The best approach currently is to use antipsychotic drugs thoughtfully for clear indications, the best supported of which, scientifically, is chronic schizophrenia. There is a search for new agents with much less adverse neurologic effect but with adequate antipsychotic efficacy. This article summarizes an APA Task Force Report.

The past two decades have produced revolutionary changes in the practice of psychiatry and in psychiatric research. Particularly striking changes have occurred in the pattern of care of psychotic and other severely disturbed patients. The introduction of effective antipsychotic drugs in the early 1950s contributed to the changes in clinical management of such patients and to diminished emphasis on long-term institutional care. The antipsychotic drugs lead to rapid control of psychotic symptoms and behavior in a wide variety of psychotic illnesses. Furthermore, such characteristics can have useful long-term preventive or ameliorative effects; however, these long-term effects have been scientifically verified only in schizophrenia.

Virtually all of the antipsychotic agents currently used in American medical practice exert undesirable neurological effects. Hence the term "neuroleptic" is often applied to this class of drugs. Most of the early neurological effects (e.g., dystonias, parkinsonism, akathisia, or motor restlessness) are spontaneously reversible or are managed by the temporary addition of an antiparkinsonian drug (1) (see table 1). However, in recent years it has been realized that there may be later development of certain neurological effects, including abnormal movements, usually of a choreoathetotic or dystonic type. These late reactions are referred to as tardive (late and gradually appearing) dyskinesia (2, 3). They can be so mild as to escape notice or can be severely disabling. In an uncertain proportion of cases, these movements persist for many months, sometimes indefinitely, even when the suspected offending agent is removed. Thus, their occurrence in association with long-term use of neuroleptic agents has become a cause of increasing concern to the medical profession and the general public.

CLINICAL DESCRIPTION, DIFFERENTIAL DIAGNOSIS, AND CLINICAL EVALUATION

Tardive dyskinesia is manifested by a wide variety of involuntary movements including orolingual dyskinesia, chorea, athetosis, dystonia, tics, and facial grimacing but excluding rhythmic tremor. The severity and extent of dyskinesias range from isolated orolingual dyskinesia to widespread and sometimes disabling dystonia. Age may influence the topographic distribution of involuntary movements; for example, oral-lingual movements are especially common in the elderly. Tardive dyskinesia may appear after months or years of treatment with neuroleptic drugs and typically worsens during or after drug withdrawal. In some cases, dyskinesias that appear during drug withdrawal subside within several weeks and are referred to as withdrawal dyskinesias (4, 5). It is possible, although unproven, that these cases represent an early and reversible form of tardive dyskinesia.

It is important to emphasize that a wide range of ab-

TABLE 1
Neurological Side Effects of Neuroleptic-Antipsychotic Drugs

Side Effect	Features	Period of Greatest Risk	Proposed Mechanism	Treatment
Acute dystonia	Spasm of muscles of tongue, face, neck, back; may mimic seizures; *not* hysteria	1–5 days	Unknown	Antiparkinsonian agents are diagnostic and curative (administered intramuscularly or intravenously, then orally)
Parkinsonism	Bradykinesia, rigidity, variable tremor, masked expression, shuffling gait	5–30 days	Dopamine blockade	Antiparkinson agents help (administered orally)
Akathisia	Motor restlessness; *not* anxiety or agitation	5–60 days	Unknown	Reduce dose or change drug; antiparkinsonian agents or benzodiazepines may help
Tardive dyskinesia	Oral-facial dyskinesia; choreoathetosis	Months–years (worse during or after drug withdrawal	May be due to functional excess of dopamine	Prevention is best; treatment is unsatisfactory
"Rabbit" syndrome	Perioral tremor (may be a late variant of parkinsonism)	Months–years	Unknown	Antiparkinsonian agents may help

normal movements that may be called tardive dyskinesia is encountered clinically. This fact complicates the definition and diagnosis of tardive dyskinesia. One of the difficulties arising from currently heightened awareness of tardive dyskinesia is greater sensitivity to minor degrees of abnormal movements, some of which may not be related to neuroleptic drug use and do not represent tardive dyskinesia. These abnormalities include minor movements that may be difficult to distinguish from habit spasms, other tics of unknown cause, psychotic mannerisms, manifestations of senescence, or even normal movements associated with ill-fitting dentures. A major problem in diagnosing tardive dyskinesia is determining the baseline of spontaneous (not neuroleptic-induced) dyskinetic movements in normal populations, the geriatric population, and the schizophrenic population; the latter two groups apparently have a greater incidence of spontaneous movement abnormalities.

Factors to be considered in differential diagnosis include schizophrenic stereotyped movements, reversible neuroleptic syndromes, and dyskinesias induced by other drugs. In addition, one should consider several other neurologic disorders that produce involuntary movements (see appendix 1).

Although it is essential that one be vigilant for early identification of tardive dyskinesia, it is important not to overlook other disorders in which psychiatric symptoms and involuntary movements may coexist and have no relationship to tardive dyskinesia. Once tardive dyskinesia is identified, efforts to rate its severity in a reliable manner are essential for future management. A number of methods exist (6), the most practical of which are multiple-item rating scales (7) topographically arranged by body area. These include the Abnormal Involuntary Movement Scale (AIMS) (8), developed at the National Institute of Mental Health, and a similar but more detailed scale developed by Simpson and colleagues (9).

TABLE 2
Prevalence of Tardive Dyskinesia, in Various Degrees of Severity, Among Chronic Schizophrenic Inpatients and Outpatients Treated with Neuroleptic Drugs[a]

Rating of Severity[b]	Approximate Percent of Patients
2.0	68
2.5	44
3.0	27
3.5	12
4.0	4

[a]Data are based on surveys of over 500 patients diagnosed as schizophrenic and evaluated in 1977 and 1978 at the Harlem Valley Psychiatric Center in Wingdale, N.Y., by Dr. J.M. Smith and his colleagues (15), who provided the data abstracted above.
[b]Severity was evaluated using the NIMH Abnormal Involuntary Movement Scale (AIMS) (8), examples of which appear in the Task Force Report. A rating of 4 in any one body area (rare) represents severe dyskinesia.

RISK FACTORS, PREVALENCE, AND OUTCOME

Epidemiologic studies strongly support an association between the use of neuroleptic drugs and the development of persistent as well as relatively transient forms of tardive dyskinesia (10). While there is some evidence that prolonged exposure or exposure to large total amounts of a drug may be a contributing factor (11, 12), this is not established. There is a very weak correlation between average daily drug dose and tardive dyskinesia (13). Older patients and women may be at higher risk and may have a poorer prognosis for eventual remission (14, 15). The aging brain may have an increased likelihood of neuroleptic-related tardive dyskinesias, especially of the oral region. Other specific predictors of risk (such as type of drug and dose,

iming of exposure, prior acute reversible extrapyramidal symptoms, use of antiparkinsonian agents, or sex) are *not clinically useful*. Moreover, it is clear hat similar exposure to neuroleptics does not produce ardive dyskinesia in all patients and that there are no groups (as defined, for example, by age or drug history) which are exempt from risk.

It is nearly impossible to specify the precise prevalence rates of tardive dyskinesia since there is no currently accepted standard for diagnosis (14, 15) (see able 2). Certainly, clinically appreciable cases occur n at least 10%–20% of the patients exposed to neuroleptic drugs for more than a year, and the rate is probably higher among the elderly. However, both the medical profession and the public should be aware that profoundly disabling, irreversible dyskinesias are uncommon. Some epidemiological studies suggesting a high prevalence of tardive dyskinesia (16, 17) may reflect an increasing sensitivity to minor degrees of possible movement abnormality. Even in the elderly, studies show that the prevalence of spontaneous buccolinguomasticatory movement abnormalities is close to that found in neuroleptic-medicated geriatric patients (18, 19). At present, it is impossible to say whether patients showing slight hyperactivity of the tongue and slight choreic movements of the fingers have tardive dyskinesia. Some abnormalities of posture and movement were reported in schizophrenic patients before the use of neuropleptics (1). Available studies have applied different criteria and have reported vastly different prevalence rates of tardive dyskinesia, ranging from less than 10% to over 50% (10, 16, 17). Fortunately, an increasing number of patients are being reported who appear to undergo spontaneous remission, usually within a period of months but up to 1–2 years, after discontinuing or decreasing the dose of the suspected offending agent; one-fourth to one-half of the patients may improve markedly within a year (20–30)[1] (see table 3).

Even if the "true" prevalence of tardive dyskinesia is between 10% and 20% of the patients treated with neuroleptic drugs for more than a year, and even if many of these patients eventually improve spontaneously after discontinuing treatment, the problem is clearly a significant one. Moreover, even mild choreoathetosis due to neuroleptic treatment is a valid cause of concern and encourages the development of safer and more selective antipsychotic drugs. On the other hand, considering the present state of knowledge, it would be an exaggeration to conclude that serious and profoundly disabling degrees of irreversible tardive dyskinesia commonly occur in current clinical practice.

ETIOLOGY AND PATHOPHYSIOLOGY

An open-minded attitude concerning the etiology of tardive dyskinesias is called for. Nevertheless, at the present time the conclusion seems inescapable that an important and relatively selective action of the antipsychotic-neuroleptic drugs is to block the actions of dopamine as a neurotransmitter in various regions of the central nervous system (CNS) (31–33). Acute extrapyramidal and sustained neuroendocrine side effects of these agents (such as increased prolactin secretion) are, in part at least, reflections of this action in the basal ganglia and hypothalamus or pituitary (34),

[1]J. Doller-Wojcek, A.J. Gelenberg, R.A. LaBrie, and associates: Outcome of tardive dyskinesia: unpublished observations at the Massachusetts General Hospital, Boston, 1980.

respectively. Antipsychotic effects may reflect antidopamine effects in limbic or cortical portions of the forebrain, although this hypothesis remains tentative (35, 36). There is also excellent evidence that prolonged exposure to antidopamine drugs can induce a variety of secondary and partially compensatory adjustments in the physiology and biochemistry of dopamine neurons and cells with which they interact in the animal or human CNS (33). Among these adjustments, some tend to *increase* the effectiveness of dopamine as a neurotransmitter, particularly in the basal ganglia. These effects may help to explain the clinical observation that the risk of acute extrapyramidal reactions diminishes in time, as the risk of tardive dyskinesia increases (1, 3). These effects are the basis of a "dopamine supersensitivity" hypothesis in tardive dyskinesia (37, 38). Further support for this hypothesis is the clinical pharmacologic evidence suggesting that a functional overactivity of extrapyramidal mechanisms mediated by dopamine is an important aspect of the clinical pathophysiology of tardive dyskinesia (see appendix 2). An explanation of the prolonged and even irreversible course of some cases of tardive dyskinesia awaits further research, especially as it suggests that irreversible neurotoxic or degenerative effects of neuroleptic agents may occur. However, these effects have not been demonstrated in postmortem neuropathological studies of animal or human brain tissue (39, 40).

While the precise cause of tardive dyskinesia remains uncertain, the study of neurological, behavioral, and endocrinological effects of neuroleptic agents on the CNS has contributed to an improved understanding of their actions, at least equal to that of many other drugs used in medicine (34, 41, 42). Moreover, insights arising from studies of the antidopamine effects of antipsychotic drugs in various brain regions promise to lead to the development of less neurotoxic but effective antipsychotic agents (42).

For the future, more work can and should be done to study the possible relationship of neuroleptic drug effects and the tardive dyskinesia syndrome. It would be helpful to have more epidemiological studies in countries where antipsychotic drugs are still not used extensively or are used in consistently different average daily doses than in the United States (43, 44). Dyskinesias follow treatment with neuroleptic-antipsychotic agents after widely differing periods of time, and they manifest various anatomical patterns and degrees of persistence. Thus, they may not necessarily represent a single disease with a unitary pathophysiology. While similar dyskinesias can occur independently in association with senile brain changes and many other overt or presumed states of CNS disease, usually there are no organic, metabolic, or neurological factors found on clinical examination that might contribute to the development of neuroleptic-related tardive dyskinesias. More attempts should be made to reproduce the dyskinetic phenomena by prolonged administration of drugs to intact animals, as well as to those with selective brain lesions, compromised cerebral circulation, or old age, and to make greater use of newer primate models of the disorder (45). There is also a need for further carefully controlled neuropathologic studies in animals and man after prolonged exposure to neuroleptic agents, using classical neurohistology and electron microscopy as well as newer techniques such as chemical assays of transmitters and their metabolites, biochemical and immunohistological assays of neuron-specific enzymes, and labeling assays for neurotransmitter and drug receptors. Such methods are applicable to postmortem human brain tissue for a more direct evaluation of the current pathophysiologic hypotheses concerning the brain's response to prolonged exposure to neuroleptics and development of tardive dyskinesia.

CONCLUSIONS AND RECOMMENDATIONS

Psychiatric chemotherapy must be based on rational guidelines that include objective evaluation of the illness to be treated, consideration of the patient's clinical history and response to treatment, an analysis of the risk-benefit ratio of any prospective agent for that patient, and a plan of action based on whether treatment is for an acute episode, sustained therapy of an active condition, or prevention of possible recrudescence of a successfully treated condition. These criteria are especially pertinent in decisions regarding sustained use (more than 6–12 months) of neuroleptic medications, since such treatment carries a risk of tardive dyskinesia.

It must be emphasized that the rational use of any form of treatment in psychiatry, as in general medicine, is based on careful diagnosis. Until recently, there was a tendency in the United States to use the term "schizophrenia" excessively broadly, almost as a synonym for "psychosis" or "severe psychiatric disorder." Thus, the diagnosis of schizophrenia was applied to many patients who would now be considered to suffer from an affective disorder, acute psychosis of uncertain type, or a personality disorder. Since diagnosis guides therapy, acceptance of a broad definition of schizophrenia probably tends to increase the use of long-term neuroleptic therapy. Prolonged neuroleptic therapy in cases other than chronic psychosis entails an increased risk of tardive dyskinesia when it may well be avoided by the use of alternative treatments. The importance of rigorous diagnosis is becoming increasingly recognized in this country and is a concern of APA, as witnessed by the current revision of its *Diagnostic and Statistical Manual (DSM-III).*

Short-Term Indications for Neuroleptics

In current American medical practice, neuroleptic medications are used for the short-term treatment of

acute psychotic episodes or for sustained maintenance or preventive therapy. Short-term use can reasonably be defined as treatment of less than 6 month's duration. The risk of persistent neurologic sequelae in this period of time appears to be small (except in rare cases of unusually sensitive patients, or perhaps with unusually high dosages). The primary indication for short-term use of a neuroleptic drug is acute psychosis, including 1) first clinical manifestation or exacerbation of schizophrenia, 2) paranoid states and other acute psychotic episodes of uncertain types (idiopathic conditions in which a categorical diagnosis is not possible) (46, 47), 3) mania, since lithium alone may not be adequate for acute reduction of manic excitement (48), 4) certain cases of toxic or organic psychosis (49), 5) childhood psychoses (50), and 6) as an adjunctive therapy in severe depressions with psychotic symptoms (51).

For treatment of manic excitement, when acute control is of primary clinical importance, neuroleptics typically are required in addition to lithium due to the latter's delayed onset of action. Evidence is mixed regarding the effectiveness of tricyclic antidepressants alone in depressions with prominent psychotic symptoms (51, 52); therefore, some patients with these disorders may be found empirically to benefit from the temporary addition of a neuroleptic agent. Nevertheless, antidepressant drugs and ECT remain the basic medical therapies with severe depression (53).

Other indications for the short-term use of neuroleptic drugs include states of acute agitation occurring in acute or chronic brain syndromes, the latter including dementia and mental retardation. Serious consideration should be given to the risks and benefits of neuroleptics compared with other drug treatments or nonpharmacologic management. In these two conditions, as with any psychotic or agitated state associated with cerebral dysfunction, patients are at greater risk for drug-induced delirium, but this risk may be less prominent with neuroleptic drugs than with sedatives (49). There are other occasional nonpsychiatric uses of neuroleptic drugs (54), including preoperative sedation, adjunctive uses in general anesthesia, and control of nausea or vertigo, as well as in the control of neurological or psychiatric manifestations of certain unusual disorders, such as Huntington's disease and Gilles de la Tourette's syndrome (55, 56). Finally, short-term treatment with neuroleptics has been used empirically in clinical psychiatric practice to ameliorate the symptoms of a variety of neurotic and characterologic disorders. The indications for this latter form of pharmacotherapy have not been developed in controlled studies; therefore, this use of neuroleptics requires critical clinical judgment in each case.

Long-Term Indications for Neuroleptics

Prolonged use (i.e., more than 6 months) of a neuroleptic medication requires careful evaluation of indications and risks. Such use is indicated for maintenance treatment of chronic psychotic disorders (mainly schizophrenia) in which the patient, although improved, is not symptom-free and is responsive to continued treatment. Sometimes prolonged neuroleptic treatment is used with Huntington's disease or Gilles de la Tourette's syndrome (55, 56), although the *long-term* efficacy and risk of such therapy require further study. While some controlled studies and substantial clinical experience support the short-term efficacy and safety of neuroleptic agents for conditions other than schizophrenia, as discussed above, there are virtually no controlled studies to verify long-term or maintenance use of these drugs with such conditions, and such use remains largely a matter of clinical judgment in individual cases. For example, it is recognized that in some cases of mania or depression with recurrent psychotic symptoms, neither lithium nor an antidepressant alone is an effective maintenance therapy and a clinical decision to try neuroleptic therapy might be considered

In general, maintenance treatment with neuroleptics is supported by scientifically sound data only for schizophrenia. The efficacy of maintenance neuroleptic medication in preventing psychotic relapse in chronic schizophrenic patients has been well demonstrated in approximately 30 controlled studies, in which an average of 56% (range=17%–100%) of nearly 3,500 patients who received placebo from 3 months to more than a year deteriorated clinically while only 17% (range=0%–49%) of the patients given a neuroleptic agent did so (57, 58). It should be noted that while this is a highly statistically significant mean difference, nearly half of the chronic schizophrenic patients did *not* deteriorate on a placebo. Studies evaluating outcome later than a year are rare. Some evidence suggests that effective doses of neuroleptic drugs during so-called maintenance treatment of schizophrenia may be lower than those in more acute phases of the psychoses (58).

In summary, commitment of a patient to treatment with neuroleptics for more than a few months requires 1) more than one acute psychotic episode without full return to optimal prepsychotic status, 2) objective evidence of continuing psychosis, or 3) good recovery but frequent recurrences that suggest the likelihood of further breakdowns, and 4) evidence of *responsiveness* to treatment. Antipsychotic drugs are to be avoided with patients who do not clearly need them or when they are not effective.

Management of Prolonged Neuroleptic Therapy

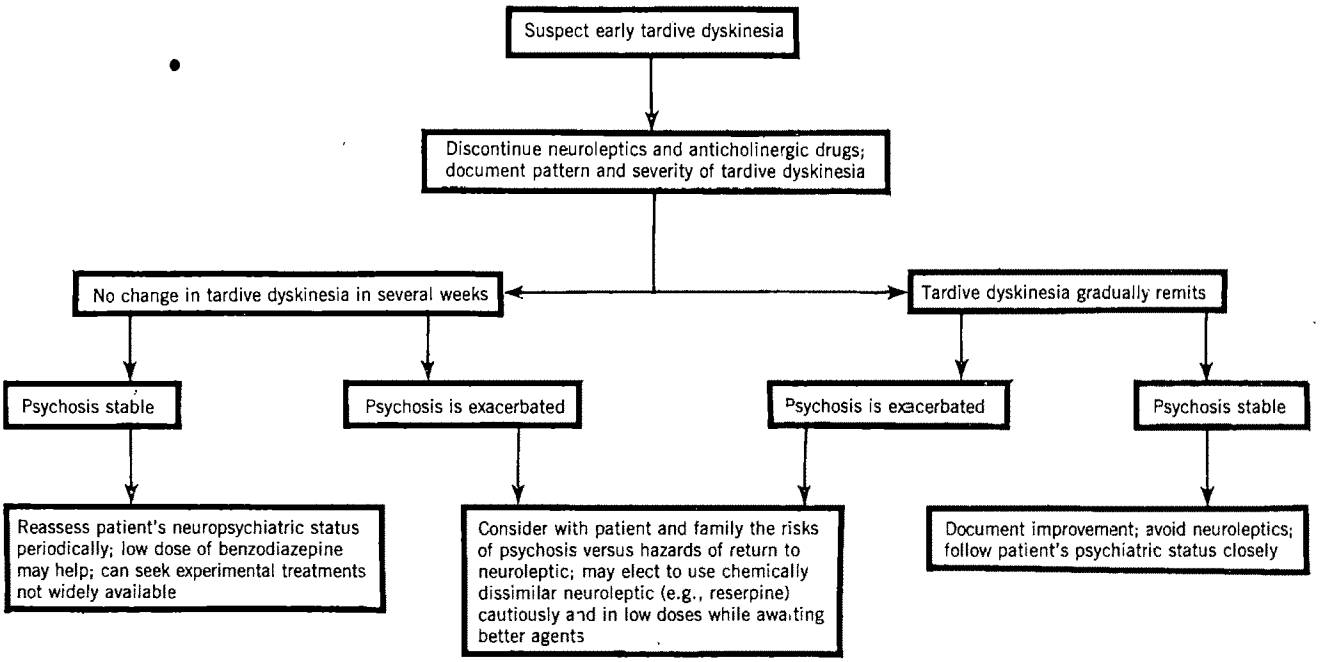
Any treatment has four potential outcomes: complete remission, partial relief, no effect, or clinical worsening. Maintenance neuroleptic treatment must be considered in light of these possible outcomes. Documentation of the continued indications and effectiveness of this treatment should be reviewed peri-

odically (at least every 3–6 months) and stated in the patient's records, with regular reconsideration of the benefits and the risk of tardive dyskinesia or other unwanted effects. At those times the patient's neurological and psychiatric status should be recorded. If there is no evidence of tardive dyskinesia, this observation is noted as a significant negative finding.

Even with schizophrenia, for which maintenance treatment has strong research support (57), deliberate and sustained effort must be made to maintain patients on the lowest effective amount of drug and to keep the treatment regimen as simple as possible. After a first acute psychotic episode of any type has clinically remitted, the dose of a neuroleptic drug should gradually be decreased and can usually be safely discontinued within several months. This recommendation is especially pertinent since it is rarely possible to diagnose schizophrenia with confidence based on a single psychotic episode. It is becoming increasingly clear that many acute psychoses eventually prove to be episodes of manic-depressive illness, which has not been demonstrated scientifically to benefit from prolonged maintenance neuroleptic treatment. Increasing the dose of a neuroleptic drug for a schizophrenic patient to unusually high levels can be supported only when smaller doses do not lead to clinical improvement and higher doses appear to be effective. The presumption in such therapy is that the degree of added benefit is thoughtfully balanced against possible additional risk of late complications.

For the special case of chronically hospitalized schizophrenic patients, it is recommended that neuroleptic medications be reevaluated at least yearly and preferably twice yearly. The dose of medication should be reduced by about 10% every 3–7 days until it has been totally discontinued or until clear signs of clinical worsening intervene. The patient should discontinue treatment for at least 2 weeks if his or her clinical status permits and if recent clinical experience does not suggest that such a trial is excessively dangerous. Such periodic evaluations serve two purposes: 1) to detect withdrawal dyskinesia, which may be a prodromal but reversible phase of tardive dyskinesia, and 2) to allow the clinician to evaluate whether continued neuroleptic use is necessary. This practice may also be tried with selected outpatients. However, the ubiquitous and critical shortage of adequate aftercare often does not permit such trials, because without medication and without close follow-up to detect early clinical signs of worsening, there is a high risk of relapse, often with serious medical and social consequences. However, the hospital setting does provide close monitoring and occasionally outpatients or day-hospital patients may be readmitted for periodic reevaluations. Even if such a trial with less medication has been unsuccessful within the past year, it still should be reconsidered at regular intervals and seriously attempted for most patients; the potential benefits outweigh the possible risks and the natural reluctance of those caring for fairly stable chronically ill patients to "rock the boat."

Some practical aspects of the prolonged use of neuroleptics, aimed at reducing the risks of late toxic effects, are summarized in appendix 3.



Management and Treatment of Tardive Dyskinesia

If a patient develops dyskinesia during a trial of reduced dosage of a neuroleptic or while fully medicated, the theoretical treatment of choice is discontinuation of neuroleptics (see figure 1). The available data suggest that tardive dyskinesia is often reversible if neuroleptics are withdrawn, especially early in its course, although some patients may require many months to improve. A dilemma is presented when a patient's psychosis is exacerbated after neuroleptic treatment is stopped and tardive dyskinesia is also present. In this situation the clinician, with the patient and family, must weigh the risk of psychiatric worsening, which may be seriously life-disrupting or even life-threatening, against the risk of tardive dyskinesia. Since tardive dyskinesia seems not to be a uniformly and relentlessly progressive neurologic disorder, it may be prudent to continue neuroleptic therapy temporarily if the psychiatric indications are sufficiently compelling. Although there is little scientific evidence to support the practice, some psychiatrists rely on less potent neuroleptic drugs with relatively less tendency to induce acute extrapyramidal effects in such situations. Clozapine had also been used in this way due to its low incidence of acute and late neurologic side effects, but this experimental agent is not available now due to other serious toxic effects associated with its use. Other safer agents are being sought, but none is yet available in American practice.

Although many therapies for tardive dyskinesia have been evaluated (see appendix 1), none has been either thoroughly studied or proven safe and effective. Discontinuation of neuroleptic medication is the theoretically ideal treatment but is not feasible for many patients. Newer investigational therapies are based on partially demonstrated increases in brain cholinergic activity (choline, lecithin, deanol) (59, 60), unproven increases in GABA-ergic activity (benzodiazepines, baclofen, sodium valproate, muscimol) (61, 62), or reduced dopaminergic activity (dopamine-blocking drugs, such as the potent neuroleptics themselves, or dopamine-depleting drugs, such as reserpine) (63, 64). It is possible that tardive dyskinesia is a heterogeneous group of disorders with a variety of anatomical, neuropathological, and pathophysiological bases, corresponding to the varieties of natural history and responses to treatment. No treatment to date uniformly benefits dyskinesias in all patients.

In short, there is no satisfactory or uniformly effective treatment for tardive dyskinesia. Recently proposed experimental treatments, notably attempts to in-

FIGURE 1
Recommended Scheme of Management of Tardive Dyskinesia

crease brain cholinergic function with deanol, choline, or lecithin, are attractive since they do not seem to worsen psychosis (theoretically they might even benefit psychosis as well as dyskinesia) (59, 60). Moreover, attempts to provide such experimental or unproven treatments (it is sometimes difficult to obtain them except in academic centers) offer a hopeful and positive approach to clinical management while the clinician and patient await a spontaneous remission of tardive dyskinesia over a period of many weeks or even months after discontinuation of neuroleptic treatment. Although increasing the dose of a potent neuroleptic may mask or suppress the dyskinetic movements, this tactic carries the theoretical risk of causing further neurologic insult. Nevertheless, this step is sometimes taken when the dyskinetic problem is severely incapacitating (similar to the practice of treating Huntington's disease or Gilles de la Tourette's syndrome).

At the present time, the best available means to deal with the problem of tardive dyskinesia is the use of conservative but effective dosage regimens of neuroleptics for clear-cut indications (continuing objective evidence of psychosis and of responsiveness to treatment).

Physician-Patient Relationship

Good practice necessitates that the psychiatrist sustain rapport with patients at risk of developing tardive dyskinesia. Furthermore, the psychiatrist is obliged to educate the patient as to the nature of his or her illness, the potential benefits of available treatments, and their potential adverse effects. Early in the treatment of a severely disturbed patient, such education may be limited by virtue of the patient's psychosis or confusion. At these times, family members or other persons close to the patient can be involved in such discussions. The need to review the treatment plan and its potential benefits and risks with the patient and his or her family becomes especially significant when prolonged neuroleptic therapy is considered or if tardive dyskinesia has already developed.

Although the routine use of signed and witnessed consent documents to protect the interests of the patient and the physician during prolonged neuroleptic therapy has been proposed, there are many problems with this approach. First, there are marked differences between established pharmacologic treatments and invasive surgical, diagnostic, or experimental procedures for which this type of formal documentation of consent is often (but not always) used. While the latter typically involve brief, acute risks during a patient's care, for which limited procedural consent can meaningfully be given, pharmacologic treatments of chronic disorders are likely to be continued and modified repeatedly over extended periods of time. Written consent would therefore not be feasible unless given in a blanket fashion, making it a potentially meaningless formal exercise. In addition, it is a precedent-setting step to routinely require written consent to institute an accepted, nonexperimental medicinal therapy. Based on these considerations, routine signing and witnessing of written consent for neuroleptic therapy is not recommended. On the other hand, good practice does require that the physician note in the records that the

indications for and risks of prolonged neuroleptic treatment have been carefully considered and reviewed with the patient or family.

Need for Further Research

A review of the present state of the medical treatment of severe chronic psychiatric disorders leaves many unanswered questions and underscores the need for further basic and applied research. There is an urgent need for the development of effective antipsychotic drugs that do not have the long-term risk of inducing tardive dyskinesia. This requires the development by academic and industrial pharmacologists of better drug screening tests (e.g., animal models that are not dependent on drug-induced extrapyramidal effects). Clozapine and sulpiride are examples of experimental drugs that seem to be effective antipsychotic agents with little acute or late extrapyramidal effect. Unfortunately, experimental trials with clozapine have been discontinued due to its association with agranulocytosis, and sulpiride is not available in the United States. Safer analogues of these or similar drugs are now being considered; their rapid development and clinical testing are strongly encouraged.

While we await the availability of more nearly ideal antipsychotic drugs, many questions still need to be answered about the use of currently available neuroleptic drugs. For example, more controlled treatment studies are needed comparing the efficacy of ECT, antidepressants, neuroleptics, and various combinations of these treatments with severely depressed patients. The safety and effectiveness of prolonged neuroleptic treatment of manic-depressive patients or others with episodic psychoses who cannot be managed with lithium alone need to be investigated. Although neuroleptics are sometimes used for patients with neuroses or character disorders and "borderline" patients, such use requires critical evaluation in research studies. Another research area in need of strong support includes various attempts to make the use of available agents for specific patients as effective as possible. Thus, more information on the dose-response relationships in man is required for all antipsychotic agents, especially to support the clinical impression that effective maintenance doses may be lower than those required for acute exacerbations of psychosis. In addition, efforts to apply available and still-evolving methods of analysis of drug metabolism and pharmacokinetics to routine clinical use are needed. While neuroleptic pharmacotherapy has greatly advanced patient care, it must be continually improved through sound clinical research.

Postgraduate Education

Although further research is required to address the many areas of uncertainty already discussed, much is already known that has a bearing on the safe and effective use of antipsychotic drugs in clinical practice. Our survey of North American psychiatric training centers indicates that the majority provide some training in clinical psychopharmacology to residents and practicing physicians. These aspects of postgraduate and continuing medical education are strongly encouraged and should be given even greater support to ensure that the best possible care will continue to be available to the most severely ill psychiatric patients.

APPENDIX 1
Differential Diagnoses to Consider in Evaluating Tardive Dyskinesia

1. Neuroleptic withdrawal-emergent dyskinesias or other transient acute dyskinesias associated with neuroleptics (see table 1).
2. Late and persistent "classical" tardive dyskinesia itself (both psychiatric disorder and dyskinesia may be present).
3. Stereotyped movements of schizophrenia (both psychiatric disorder and dyskinesia may be present).
4. Spontaneous oral dyskinesias of advanced age or senility (both psychiatric disorder and dyskinesia may be present).
5. Oral dyskinesias related to dental conditions or prostheses.
6. Idiopathic torsion dystonia.
7. Focal dystonias (bromandibular dystonia, blepharospasm, spasmodic torticollis) and habit spasms (tics).
8. Huntington's disease (both psychiatric disorder and dyskinesia may be present).
9. Gilles de la Tourette's syndrome.
10. Wilson's disease (hepato-cerebral-lenticular degeneration due to abnormal copper metabolism), manganism, and other disorders due to heavy metal poisoning (both psychiatric disorder and dyskinesia may be present).

11. Fahr's syndrome and other disorders with calcification of the basal ganglia.
12. Postanoxic, postencephalitic, and encephalitic extrapyramidal syndromes (both psychiatric disorder and dyskinesia may be present).
13. Rheumatic chorea (Sydenham's chorea, St. Vitus' dance).
14. Drug intoxications involving L-dopa and amphetamines and, less commonly, anticholinergics, antidepressants, lithium, and phenytoin (both psychiatric disorder and dyskinesia may be present).
15. CNS complications of systemic metabolic disorders, such as hepatic or renal failure, hyperthyroidism, hypoparathyroidism, hypoglycemia, and vasculitides (both psychiatric disorder and dyskinesia may be present).
16. Brain neoplasm (thalamic, basal ganglia).

APPENDIX 2
The Differential Pharmacology of Tardive Dyskinesia[a]

AGENTS THAT MAY PARTIALLY SUPPRESS TARDIVE DYSKINESIA

Dopamine antagonists
- Apomorphine (in low dose)
- Butyrophenones
- Clozapine
- Papaverine (mechanism uncertain)
- Phenothiazines
- Pimozide

Amine-depleting agents
- Reserpine
- Tetrabenazine

Blockers of catecholamine synthesis
- Alpha-methyldopa
- Alpha-methyltyrosine

Blockers of catecholamine release
- Lithium salts

Cholinergic agents
- Deanol (mechanism uncertain)
- Choline and lecithin (phosphatidylcholine)
- Physostigmine

Miscellaneous agents
- Baclofen (postulated GABA mechanism unproven)
- Valproate (postulated GABA mechanism unproven)

Muscimol

AGENTS WITH VARIABLE, NEGLIGIBLE, OR UNCERTAIN EFFECTS

Alpha-methyldopa
Amantadine
Antihistamines
Barbiturates
Benzodiazepines
Cyproheptadine
Deanol
Isocarboxazid
Methylphenidate
Penicillamine
Physostigmine
Pyridoxine (vitamin B_6)
Tryptophan

AGENTS THAT WORSEN TARDIVE DYSKINESIA

Anticholinergic agents
- Antiparkinsonian agents (e.g., benztropine)

Dopamine agonists
- Amphetamines
- L-Dopa (may have opposite effect in small, repeated doses)

Other agents
- Phenytoin

[a]Some drugs appear in more than one category, reflecting ambiguity in the literature. Note that while apomorphine is usually classified as a dopamine-agonist, it actually has complex mixed actions, may antagonize dopamine at low doses, and has clear antidyskinetic effects.

APPENDIX 3
Suggested Guidelines for the Avoidance and Management of Tardive Dyskinesia

1. Consider carefully the indications for prolonged neuroleptic therapy; the indications should be serious (e.g., chronic psychosis), and there should be objective evidence of benefit.
2. Seek alternative therapies with neuroses and mood and character disorders.
3. Use lower doses with elderly patients and children; strive for minimum effective doses; avoid multiple drugs; discontinue antiparkinsonian agents as soon as possible.
4. Advise patients and families of risks and benefits; arrive at a mutual decision when use of neuroleptic exceeds 1 year. Note discussion and agreement in clinical record.
5. Examine patient regularly for early signs of choreoathetosis and oral-lingual dyskinesia. Consider alternative neurologic diagnoses.
6. Reevaluate patient and document indications and response at least every 3–6 months and attempt to reduce dose.
7. At earliest sign of dyskinesia, lower the dose, change to a less potent agent, or, ideally, stop treatment; await remission as long as psychiatric status permits.
8. Treat dyskinesia with benign agents first (e.g., diazepam, deanol, choline, or lecithin in high doses, possibly lithium); stay alert to new experimental therapies, if only to bide for time and offer hope. Reinstitute neuroleptics only as an extreme measure for disabling dyskinesias, using lowest doses feasible.

The Unstated Problem in a Psychological Testing Referral

BY LESLIE JORDAN COHEN, PH.D.

There is a manifest and a latent content to many psychological testing referrals. Although a diagnostic problem is usually the stated reason for the referral, the unstated and more basic reason frequently has to do with problems the therapist is encountering in attempting to deal with a difficult treatment situation. The testing psychologist who responds at the manifest level alone may not help and at times may even be a hindrance.

Psychiatrists tend to think of psychological testing as a procedure for establishing diagnosis. Their usual assumption is that a case is referred for testing because it poses a diagnostic problem, and psychologists tend to share this view. Psychologists are often trained to think of themselves as possessing in their test instruments the tools to make subtle diagnostic differentiations that might elude psychiatrists with their more "impressionistic" methods of mental status exam and clinical interview. A request for testing phrased in terms of the need for diagnosis fits into everyone's conception of a straightforward testing referral.

A consult sheet directed to the testing psychologist frequently asks for a diagnosis in *DSM-II* terms, with such questions as "Is this patient manic-depressive?" or "Is this a functional or an organic psychosis?" Sometimes the referral question is stated in what might be called diagnostic building block terms, with such questions as "Are there ego deficits?" or "Is there evidence of depression?" Phrased either way, such questions imply that the psychiatrist is experiencing an uncertainty about the case that diagnostic information would help to resolve. The psychologist does his or her best to give thorough answers to these questions.

Even when the referral appears straightforward, however, it is my impression that psychologists and psychiatrists are not infrequently frustrated in their efforts at collaboration. After the work is completed and a testing report entered in the chart, the psychiatrist might be saying to himself, "This report is long and very academic but of not much practical value; it basically does not tell me anything I did not know already." The psychologist might conclude that his or her special skills simply went unrecognized by a practitioner who could not appreciate them. Both sides may be right, but I think in many cases both sides are missing the most important issue. In my own sample of testing referrals, in only a small percentage of cases does the referral question completely state the problem that the therapist needs help with. That is, in only a small portion of cases is it a clear-cut diagnostic problem that has prompted the request for testing.

Testing referrals can be thought of as falling along a hypothetical continuum. At one end of the continuum are the cases where a definitive diagnosis is of crucial importance to the referring physician, and on the other end are the cases in which it is of no practical value at all. On the end where diagnosis is crucial would fall those cases in which proper treatment depends directly on diagnosis, i.e., where treatment carried out under the assumption of an incorrect diagnosis would be not only ineffective but injurious to the patient. An example would be a case of a patient with a brain tumor who is mistakenly being treated for schizophrenia. A little further along the continuum are cases where diagnosis may be more or less important depending on the therapist's treatment orientation. If the therapist is of the opinion that some classes of psychopathology are best treated in certain specific ways—for example, schizophrenia with phenothiazines, psychotic depression with electroshock, certain forms of manic-depressive illness with lithium—then a specific *DSM-II* diagnosis becomes important.

For the therapist whose basic treatment approach is a psychodynamic one, that is, when the main treatment variables to be worked with are unconscious conflict and defense, most cases fall toward the end of the continuum where precise diagnosis is of diminishing importance. For many of the cases a dynamically oriented therapist sets about to treat, there is not a one-to-one relationship between the patient's diagnosis and the thinking involved in mapping out a treatment strategy. In order to work out a modus operandi for treatment, the therapist must solve the problems not so much of diagnosis but of the very individual and specific ways the diagnosis expresses itself in the trea-

Presented at a meeting for staff psychiatrists, Mount Airy Psychiatric Hospital, Denver, Colo., April 25, 1979. Received Aug. 6, 1979; accepted Dec. 4, 1979.

Dr. Cohen is a clinical psychologist in private practice.

ment situation. The issues that become crucial to understand include how the patient experiences the therapist in the transference, including specific transference fantasies, the basic anxiety that the patient is avoiding and which ultimately must be interpreted, the often times subtle, individualized ways the patient defends against anxiety, and the like.

Although testing referrals tend to be phrased in terms of the need for diagnosis, it is problems in the area of doing this broader and more individualized assessment that at bottom constitute the difficulty of the case and what often cause it to be referred for testing. Thus, one might say that there is a manifest and a latent content to many testing referrals. If the request for testing is responded to in terms of the manifest content alone, i.e., in terms of a diagnosis, it frequently does not go very far in helping the psychiatrist identify the underlying treatment issues that make the case a problematic one.

CLINICAL EXAMPLES

I will give three clinical examples to illustrate this situation. The first is a case where the referral request was "Rule out schizophrenia." The psychiatrist was called at night by the patient's husband with an urgent request for hospitalization. For some weeks this young woman had been accusing her husband of acting improperly toward his niece. The husband explained to the psychiatrist that there was no truth to these accusations, but he had been unable to convince his wife of this. On this particular night she had gone into a rage, shrieked her intention to kill herself, and had apparently overdosed on pills. Once admitted to the hospital, the patient quickly became enraged and demanding and at times exhibited bizarre behavior; the psychiatrist was called repeatedly by the staff for measures to handle her. The psychiatrist, who was making efforts to settle down his new patient first through ordering medication, then restraints, then seclusion, and finally a court order when she announced her intention of leaving, found himself quickly in the same role as her husband had been—the object of her rage and suspicion. He wondered if he had become the focus of a psychotic transference in a paranoid schizophrenic woman. After several days of hospitalization, when she stopped raging at him and treated him with aloofness, he wondered if this was a manifestation of "flattened affect" and further evidence of schizophrenia. It was at this point that he made the testing referral.

The testing psychologist is in a unique position when called into a case like this. He or she has the luxury of being able to do an evaluation at leisure, is spared the responsibilities of handling the case, and is often exempt from the intense transference reactions that are focused on the psychiatrist as primary therapist. In this position, and with the added benefit of standardized or semistandardized instruments to lean on, it is at times easier for the testing psychologist to maintain an objective outlook than it is for the primary therapist, who is in the thick of things therapeutically. In this case, the patient showed no signs of schizophrenic thinking in her test protocol or behavior. What did emerge was a woman with a hysterical character who was prone to dramatic emotional storms, and who had an especially painful vulnerability to narcissistic injury and feelings of humiliation with men. Her psychiatrist's efforts to treat her with restraining measures had intensified her humiliation and made her feel justified in unleasing her fury toward him in whatever way she could think of.

Having arrived at this diagnostic conclusion, the testing psychologist is able to respond to the referral question at the manifest level, but how much it will help the therapist to be told that his patient is not schizophrenic is a moot point. In fact, at the point where he requested testing, he might have been relieved if a diagnosis of schizophrenia had turned up; it at least would have given him a handle for understanding a very difficult case. The latent problems behind the referral, and those that the psychiatrist is still left with, have to do with this patient's need to act out her rage and humiliation and to pressure others to act it out with her. The psychiatrist is pressured to abandon his observing therapeutic stance and to involve himself with her in the role of a humiliating, punishing father figure, the role which she expects of all men. Without realizing it, he has acted out this role. She pays him back by becoming more and more emotional, humiliating herself further, and making him out to be ineffectual by defying his efforts to stop her.

The patient's defensive need to provoke her psychiatrist into this kind of position can be expected to come up repeatedly in any effort to treat her. Therefore, the psychiatrist's basic problem, and the unstated problem behind this testing referral, is finding techniques to help the patient understand this need in herself rather than acting it out with her.

In another case, the psychiatrist telephoned with the following request:

> Please evaluate this adolescent boy for impulsivity and possible ego defects. He has run away from home three times in the past two months. By the way, can you get to the testing by tomorrow? I promised this boy he would only be detained in the hospital three days if he would consent not to run away for that length of time. I think this boy is really upset underneath it all, and I can't afford to lose him.

The referral question is quoted in full because it nicely illustrates how the manifest referral question—the request for an assessment of impulsivity—is embedded in the context of a therapeutic dilemma. The boy, who sounds like he may be a past master at externalizing his unhappiness, has already caught the

psychiatrist up in a transference-countertransference bind in which the therapist feels he has to chase around after the patient and cajole him into doing something for himself. In this position, the boy is basically in control and the therapist fears he may lose the case.

Although the therapist phrases his referral in terms of the need for diagnosis, it is clear in this case that he has already diagnosed the patient's major ego problem. He knows that the boy is impulsive. His implicit question is what to do about it. How does he handle an impulsive boy? How does he build an alliance with someone who makes as a precondition for treatment that he be cajoled and bargained with? Clearly, these are the problems that have him stumped, not the diagnosis.

However, the fact that the referral question is posed in terms of a diagnostic dilemma when the psychiatrist already knows the diagnosis suggests that there is a defense operating. For whatever reasons, it is apparently hard for the therapist to acknowledge to himself that he is having difficulty handling the case. This in turn poses a problem for the psychologist in terms of how to respond to the referral. If he responds in terms of the manifest question and gives diagnostic information, he is at best being academically correct. But to what purpose? The report is of little practical value, since it tells the psychiatrist something he already knows. If the psychologist attempts to give technical advice, he or she is bound to run up against the psychiatrist's defenses and to be experienced as intrusive and presumptuous. This kind of dilemma makes for tension between psychiatrist and psychologist.

In the final clinical example, the psychiatrist asked in his referral for testing whether there was evidence of depression and/or borderline pathology in his female patient. When I arrived for the first testing appointment, I realized that I had walked into a battle between the patient and her therapist and that I was expected to be the arbiter. The patient greeted me by saying, "My psychiatrist says I am depressed, and I say I am not. I think I'm ready to leave the hospital, but he says I can't because I'm mentally ill. I want you to tell him that he's wrong."

I tried to learn what had led up to this battle. The patient had entered treatment some months earlier because of a severe letdown and feelings of anxiety after the youngest of her three children started grade school. While her children were young, she had felt charged with self-confidence, but their reaching school age left her feeling empty and fearing that she would ever after be directionless in life. When she began treatment, which was at first on an outpatient basis, she reported that she quickly got in touch with feelings of rage toward her own hypercritical and controlling mother; she had apparently developed a mother transference toward her therapist around that time, too. With the therapist she remembered longing for unmitigated praise and reassurance, and felt deflated and angry when she did not get this from him. She called him between sessions saying if he did not "give her something" she was afraid of how depressed she might become. He gave her medications, in increasing dosages, as the between-session calls and demands for reassurance escalated. Finally, he told her that outpatient therapy was not sufficient and suggested hospitalization. She panicked; in her mind, her therapist was confirming her worst fear, that she was very sick and on a downhill course from which she would not recover. She declined hospitalization, but by this time he was insisting on it, saying she was too ill to make her own decisions. The battle had begun in earnest. By the time the testing referral was made, the patient had adopted a position that she was, in her words, "just fine, with no mental illness, no defense mechanisms working, and no signs of depression." She felt furious with her psychiatrist who, with threats and angry confrontations, was trying to force her out of her denial.

This is a testing referral which falls on that end of the continuum where diagnosis is of no practical value at all. Both therapist and patient are seeking diagnostic information not as a means for understanding something together, but as a weapon to force the other to capitulate. For the psychologist in this situation, it is hard to see how responding in terms of diagnosis could do anything but intensify the pitch of the battle. Furthermore, this is another case where the psychiatrist seems to have a good enough understanding of the diagnosis before he requests testing. He knows that she has problems with ego functioning, relies on blanket denial, and fears she will be overwhelmed if any feelings seep through. He knows she is dealing with individuation issues in the transference and that she experiences feelings of emptiness when he cannot be with her or do her thinking for her. The problem for him is not in identifying these weak points but in knowing how to deal with them. How can he treat someone who has a phobic attitude toward uncovering her own feelings? How does he help her deal with anxiety over separations? How can he avoid taking the role of an intrusive mother when his patient's behavior seems to be pushing him into it? These are the real problems behind this testing referral.

What can be concluded about the usefulness of psychological testing in cases such as those I have presented? Optimally, simply answering the manifest referral question can serve as an injection of diagnostic reality for the therapist, who can then go on to reassess the underlying treatment issues for himself. This was the situation in the first referral I described, where testing was requested to rule out schizophrenia. Once the hysterical nature of his patient's symptoms was brought back into perspective, the psychiatrist was less alarmed by the patient's outbursts and in a far better position to empathize and understand them with her.

The process does not always work this smoothly, however. Sometimes the countertransference has become too intense or the technical problems too complex to yield without being directly identified and discussed. This was the situation in the last case. Unfortunately it is rare, when the latent referral problems need to be opened up for discussion, to have the kind of collaborative relationship between psychiatrist and psychologist that can make such discussion comfortable and productive. Often the two have not met face to face but communicate by means of consult sheets or telephone calls. The psychiatrist may resist discussion of the therapeutic problems for defensive reasons. The psychologist, too, may have learning problems and resistances that hamper his or her effectiveness. Commonly, the psychologist is so focused on demonstrating diagnostic expertise that he or she fails to appreciate situations where such expertise is irrelevant. If there are resistances on each side, the testing can turn into an exercise for confirming the defensive perceptions of everyone involved, including those of the patient, and thereby actually contribute to the difficulty of the treatment situation. It seems that the more both sides can develop a readiness to listen for the latent reasons behind a referral, the more likely testing can turn out to be a genuinely useful consultation.

Curt P. Richter Prize in Psychoneuroendocrinology

Through the generosity of the Irish Foundation for Human Development, an annual prize has been established for meritorious research in the area of psychoneuroendocrinology. The sum of $1,000 will be awarded annually for the best essay or manuscript (original research or a review article including research) submitted by a scientist or physician under 35 years of age by January 1 of the year of the award. The winning paper must be in a format suitable for publication in *Psychoneuroendocrinology*, the journal in which the winning paper will be published. The aim of the prize is to encourage younger scientists to contribute to this interdisciplinary field.

Manuscripts should be submitted in *quadruplicate* to

Dr. Fleur L. Strand, Secretary
International Society of Psychoneuroendocrinology
Biology Department, New York University
Washington Square, New York, N.Y. 10003

All submissions will be screened by a broad committee of established psychoneuroendocrinologists. The deadline for submission is January 2, 1981.

The Father's Parenting Experience in Divorce

BY HENRY J. FRIEDMAN, M.D.

The author discusses the father-child relationship as it is influenced by divorce. Psychiatrists are often consulted by individuals considering divorce who are concerned about its probable impact on their children. Data gathered from the treatment of fathers during divorce indicate that there can be positive changes in their parental bonds as a result of increased opportunities to relate to children in a conflict-free atmosphere. In such a setting, the father's nurturing experience provides him with a new perspective on parenting. Psychotherapeutic help can lead to a strengthening of parental bonds, with subsequent benefits to both father and child. The author encourages professionals to support men in improving their fathering during the postdivorce period.

Despite the currents of social change, or perhaps because of them, the literature on divorce and family life has tended to favor conservative and even reactionary views about the effects of divorce on child development and parental functioning. Many authorities consider an intact family unquestionably preferable to separation and divorce (1, 2). Authors who conclude their presentations with a cautionary statement that they are not opposed to divorce as a solution to marital conflict still fail to differentiate adequately divorce situations wherein optimum personality structure in the parents leads to a very different outcome than is seen in other divorce situations (3). It is peculiar that despite our experience with the negative effects of persistently conflictual marriages on the development of patients we treat as adults, no attempt has been made to identify the potentially positive effects of divorce on child-parent relationships.

The regrettable absence of such an approach is compounded by a tendency in the psychoanalytic literature to underemphasize the father's role in child development. In a 1973 paper, Burlingham (4) presented material about the role of fathers in the lives of preoedipal children. Although she acknowledged a greater possible role for the father, she continued to maintain that the preferred pattern for development was based on predominantly "feminine" mothers and "masculine" fathers. Burlingham indicated that blurring of feminine and masculine responsibility could lead to a "decrease in variety of experience which might well prove to be a loss to the child and show up later in the development of a flatter, more uniform and less rich affective life." Furthermore, according to Burlingham, the father's interest in nurturing a new offspring seemed to be based on a pathologic feminine identification and competitiveness with the mother.

The purpose of this paper is to discuss the possibilities of positive effects of divorce on the father's experience as a parent. Improvement in the father-child relationship is a possible outcome in many divorces, particularly if the children are young. Divorce increases the possibility for an intensified parental bonding experience through the father's opportunity to do more direct nurturing. I will attempt to present a perspective on the experience of divorce as a possibly positive adaptational experience that can give fathers the opportunity for increased nurturing experience and hence greater intuitive appreciation of their child's growth and development. The importance of a nurturing relationship for the development of an adequate bond between father and child has rarely been acknowledged, while the emphasis on good mothering as a necessity for future health has been a constant theme. There is an element of the nurturing experience that goes beyond providing the basic requirements for the child's development. The importance to the child of being nurtured by the father resides in the increased attachment of the father to the child and the resultant increase in paternal intuition. That later paternal attachment might be enhanced by fathers having intense bodily responsibility for their children in infancy seems axiomatic but has not been widely acknowledged.

The divorced father faces a crucial choice about his involvement with his children. Unfortunately, until recently custody and visitation arrangements tended toward minimal paternal involvement. Now that this has changed, more fathers are having to face the intricacies of a parenting role. In this paper I will emphasize the role of psychotherapists in helping fathers en-

Presented at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12-18, 1979. Received May 18, 1979; accepted Sept. 21, 1979.

hance their participation with children. I will also discuss the sexual confusion, fear, and withdrawal from the parental role that often interfere with a father's positive adaptational response but can be ameliorated by proper clarifications in psychotherapy.

Psychiatrists are in the unique position of seeing parents in various stages of marriage, separation, and divorce. Although we see a wide range of disturbed reactions, we also observe situations in which there can be a strengthening and even improvement of a father's roles in his children's lives. When parents seen in individual psychotherapy assert that they are staying in a marriage for the children's sake, one often sees a pattern in the fathers of overwork, absence from the home, and a tendency to give over control of the children to the wife. It is unlikely that high-level intensive fathering is occurring in such situations, even though there is no overt split between the parents.

Adult patients who have grown up in homes with unhappily married parents almost always report fantasies and wishes that their parents had separated in order to reduce tension and possibly permit a more harmonious relationship with each parent. Often this picture seems quite compatible with the therapist's speculations about what might have happened had a divorce actually occurred.

THE FATHER IN A CONFLICTUAL MARRIAGE

Burlingham (4) noted that "during the last and beginning of this century it was considered unsuitable for a father to be openly involved with the infant's care, as if taking the maternal role in this respect was undignified for a man and betrayed a lack of masculinity." While Burlingham acknowledged some shift from this extreme position in the English fathers she observed, she was skeptical about the changes apparently occurring in the liberated upper-middle-class families of the United States. In fact, the fathers she described would be considered unacceptable as parenting partners in marriages between compatible, loving adults in this country. Improved family planning and greater equality in decision making and in sharing economic burdens have meant that fathers are no longer remote "instrumental" figures (5). Fathers in the modern intact, educated family have a far greater share in the actual handling, feeding, bathing, and clothing of the newborn infant. Of course, when both parents adhere to a strict division of function, the importance of the father's role is delayed and often diminished. However, with more women returning to work soon after childbirth, sharing (not blurring) of child care responsibilities has become more the rule than the exception.

In families where incompatibility of emotional needs is reflected in overt or covert conflict, optimum sharing rarely occurs. Instead one sees some estrangement of the father from the newborn child. When marital tensions are chronic, the development of the father-child relationship is disturbed. Although few patients are in treatment for sufficient time to observe this deterioration at each stage of the father-child relationship, it is possible to reconstruct from male patients at various stages the deviations from optimum parenting style. If the conflicts between the parents remain unresolved and the marriage continues, there is a tendency for the father to become a shadowy, less significant parental figure.

CASE REPORTS

Case examples illustrating the nature of the father-child relationship in various stages of divorce are presented to show that the effects on the child-parent interaction are not always negative. When the father is in analytic psychotherapy or analysis, as were the two men described herein, it is possible both to study the nature of the father-child interaction and to influence it through therapeutic interaction. Of course, the results obtained in the cases I will describe are unusual in that patients capable of being in intensive therapy often have better developed ego capacities for experiencing emotion and modifying their interactions with others.

Case 1. Mr. A, a 35-year-old professional man, entered treatment because of marital discord. His wife was spending increasing amounts of time away from the home and becoming involved with younger colleagues from her work. Mr. A had responded to his wife's absences from the home, most of which were for social activities, with increasing exasperation, temper tantrums, and depressive affect. He had, however, remained active in his profession and was quite successful despite his personal unhappiness.

On closer examination, the marriage appeared to have been unsatisfactory in many ways before Mrs. A began to move away from her husband. She did not admire his considerable accomplishments and in fact resented the demands of his professional life. The couple had two children, ages 8 and 5 when Mr. A's treatment began.

As treatment proceeded it became clear that the patient was seen by his children as an intrusive, frightening, and unpleasant individual, a perception that had much basis in their interactions with him. Mr. A worked long hours and was seldom at home. He often returned to be faced with the children's fighting or uncooperative behavior. He tended to blow up at the children and yell at them for their inadequacies. Mr. A seldom took the time to understand the complexity of his interactions and often displaced his anger from his wife to the children. As a result, he seldom had a pleasant interaction with the children. Although he was sentimental about them, it seemed unlikely that there could be much basis for actual positive feeling on their part. The children gave many indications that they were content with their father's absences from the home.

In treatment Mr. A's attention was drawn to the basic nature of his interaction with the children, which focused on irritability and harassment rather than understanding and caring. Even when the marital discord decreased, Mr. A's

relationship with the children remained vaguely troubled. He could not understand their "childish" responses to each other, their "dawdling," and their frequent tearfulness.

Eventually Mr. A decided to end his marriage. At the time of separation he did not have much feeling about leaving his children; he seemed more like a single man looking forward to a life of freedom. However, on the therapist's urging, Mr. A declined job offers in other cites and took up residence within walking distance of the family home. He spent time investigating private schools for one of his daughters and eventually arranged for her to attend a school much better suited to her developmental needs.

The children began to be more real for Mr. A as he faced taking care of them on his own without the interference of his conflict with his wife. He realized that in the past his attention to the children's problems had often led to arguments with his wife, so he never saw his interventions and interactions with them through to a successful conclusion. He could now experience his emotional needs for closeness with his children. The therapy has continued, with evidence that a real parent-child relationship is developing.

Case 2. Mr. B's history is presented to show the fallacy of assuming that a father's continued presence in the home, despite severe marital conflict, is helpful in developing an adequate father-child relationship. As is often true in divorce, one spouse (the wife in this case) had a subtle but severe pathology.

Mr. B was an administrator in his late 40s who sought treatment for chronic depression, work inhibition and ineffectiveness, and distress related to his recent loss of another important position. The patient felt that he often failed to accomplish important work tasks despite direct pressures, and he had in fact been fired for this reason. He expressed his feelings about his failure primarily in terms of disappointing his wife. Although Mr. B described her as an excellent wife, she did not meet what would ordinarily be considered the standards of reasonable companionship. Mrs. B was chronically angry and depressed and blamed the patient for her distressed state.

The couple had two children who were adolescents at the time of the treatment. Mr. B had no relationship at all with the children, who had formed an almost symbiotic bond with their mother. Although Mr. B said he got along better with his older daughter, she seemed extremely narcissistic in her relationship to him, not caring much about his wants or needs. The younger daughter was heavily allied with her mother; Mr. B said she shared her mother's every whim and was concerned exclusively with her comfort and needs rather than those of her father. As the patient began to reflect on his relationship with his children, his sadness was intense. He had always been aware of some marital unhappiness, but he had felt certain that he must remain in the marriage for the children's sake. When he had worked through his feelings about his relationship with his children sufficiently, Mr. B felt able to leave his wife and to give up the illusion of a satisfactory relationship with his children.

The effects of the separation seemed largely positive, within the confines imposed by the established preference of the children for their mother. However, for the first time Mr. B can see some positive aspects in his relationship with both children as they are forced to develop some relationship as individuals.

EARLY DIVORCE AS A MODE OF CONFLICT RESOLUTION

If in a disturbed couple the father tends to withdraw or is excluded by the mother, one can hypothesize that the normal attachment process of father to child or child to father will be hampered. Divorced fathers who take complete care of their infant offspring, at least on a part-time basis, have a special opportunity to experience the child in an intimate setting. Men in conflictual marriages, and possibly in most marital relationships, may view their relative passivity in regard to using their full capacity as nurturing, caring figures as a reasonable response to their children. Although some attention has been paid to the need for men's liberation from rigid role models, this has not been done with the same intensity or ferment that has attended the reexamination of the woman's role. However, there is some indication from social observation that many fathers are becoming more aware of their children emotionally, particularly of the importance to their narcissism of their children's caring responses. The father involved in separation and divorce often reports a new awareness of the joys of child care. Fathers who might have bathed, fed, and comforted their children only on occasion within the marriage may find themselves doing such things regularly, with very positive results. Orthner and associates (6), in their study of fathers with exclusive custody, reported that "if there is one most impressive conclusion we can make from our interviews with these single parent fathers it is this: These fathers feel quite capable and successful in their ability to be the primary parent of their children." These researchers were clearly surprised by their finding that fathers did quite well tending to their children on their own.

FACTORS IN A FATHER'S POSITIVE ADJUSTMENT TO DIVORCE

Although fathers in the United States may hold, handle, bathe, and feed their children during the first year of life—serving as perfectly acceptable alternative caretakers—this is often done only on rare occasions and as a "favor" to the mother. There is often no necessity for the father to exercise his potential for caretaking in the intact family. When the mother works, caretaking may be relegated to another family member or to a paid caretaker.

In severely conflicted marriages, pregnancies and births still occur. The birth of a child may increase the marital estrangement, but it is fairly unusual for separations and divorce to occur when there are children under 1 year of age. There are several probable causes for this fact. First, even in difficult marriages, a pregnancy may be an attempt to forestall an actual break. After the birth of the infant, the mother's physical

needs and vulnerability may delay a separation through a combination of both neurotic and reality factors. Possibilities of separation increase during the child's second year of life. If it is hypothesized that direct care of the infant increases the father's attachment, then this may be an optimal time for the change to occur. When children are older, the opportunities for increased intensity of attachment are limited by family alliances (usually stronger to the mother) that have formed during the earlier years. Further, the older child is at a developmental stage in which his or her energies are directed away from the primary object in general. The newly divorced or separated father with a child under 2 years of age or several children under 5 years of age faces his own developmental challenge as well as an opportunity to expand his experience of his children. In cases of later separation the father may be able to separate himself from a morass of strife that has prevented him from conveying to his child a clear image of who he is and to receive from the child a relatively uncontaminated response that depends on adequate separation from the mother.

The challenge of single fathers revolves around an issue of sexual role identity. Lerner (7) has noted that sexual role stereotypes are more adaptive for individuals whose sexual identity is weak or brittle. The man who can do nothing that is identified culturally as feminine and the woman who cannot engage in any activities commonly identified as masculine represent, according to Lerner (7), the less healthy end of the sexual identity spectrum. Men who adhere rigidly to narrow, demanding views of masculinity are unable to take advantage of the opportunity of being a "separate" parent. These men tend to withdraw from their children or see them very little for a period after the separation. This withdrawal may persist until the children have reached an age where they no longer require "maternal" care. Unfortunately, such men often view psychotherapy as threatening to their masculinity and avoid treatment as something unacceptable to their view of themselves as men. Men burdened with this machismo syndrome, which consists of rigid adherence to a narrow set of male characteristics and an insistence that certain activities are exclusively masculine or feminine, are often forced into quickly finding a new woman to depend on. The dependency is expressed in terms of activities that "must" be done by women (cooking, cleaning, arranging a social calendar, doing the laundry), not in terms of closeness to another person. Since there are so many single and divorced women in our culture, men with such needs often find a female replacement for the lost, discarded, or rejecting wife quickly. This woman is then used as the new caretaker for any small children during periods of visitation.

The centrality of a flexible sexual identity for single fathers cannot be overestimated. Only with such flexibility is a new form of male parenting related to the divorce experience possible (8, 9). It is curious that our profession has shown so little concern about this concept. In their book on part-time fathers, Atkin and Rubin (10) described their method of helping fathers adjust to the arduous task of being with their children. They try to teach fathers how to be comfortable with children for whom they must care during visitation periods. It is clear from the authors' examples that they deal largely with men who have had little experience with the requirements and joys of maintaining a house and feeding and clothing small children. In my clinical experience men are not always so rigid and often have started on their own to achieve the special relationship that can occur when a father cares directly and exclusively for his child. Current custody practices are such that it is still rare for a father to obtain exclusive custody of small children unless the mother refuses custody or is declared unfit. On the other hand, men are increasingly asking for and obtaining joint custody or a much greater level of visitation. A concerned father may see his child for two or three days a week, often on weekends, during which time he is responsible for the physical care, entertainment, and understanding of the child. Contrary to what might be expected, if separation experiences are early and consistent, the young child usually makes an intense and satisfactory attachment to the father. The father who is open to and unthreatened by the nurturing role begins to experience what have been described as maternal feelings. The "in-tuneness" of the good mother becomes a part of his ego capacities. It is difficult to describe a man's discovery that his nurturing capacities are greater than he had anticipated. Furthermore, this intricate and intense understanding of the child is something that "normal" fathers may persistently lack.

Divorced fathers who have an opportunity to live with their children as caretaking parents rather than Sunday afternoon baby-sitters also report that their sense of loss and alienation as a result of the divorce has been lessened. They describe a different and far less intense or absent experience of loss resulting from this experience with their children. Many of these men report great pleasure with the parenting experience and voice regret that they did not have this experience sooner.

The importance of this new form of attachment for men lies in sharing an intensity of experience that was largely the domain of mothers in the past. This has to do not only with socially conditioned patterns of parenting but with the fact that the early symbiotic union is a basis for empathic understanding of subsequent childhood development. The father who knows his young child is more inclined to be aware of the phase-specific problems and conflicts of each developmental stage and, later, to recognize the child's transition in latency to a more adult sensibility. Awareness of the child's personhood is intensified, and the special nature of the father-child unit is increased. This special

quality deserves further consideration. The divorced father who has had considerable contact with his child thinks and feels more like a traditional mother, who is never far from including the child in some way in her emotional life. Fathers—and mothers—fantasize about the child's inclusion at a social event, on a trip, or on summer vacation. Furthermore, there is beginning to be support in the social milieu for the importance of the father-child relationship. Friends and relatives ask about the child by name, and schools have started to include the father in a much more direct and meaningful way.

Of course, parenting is never free from ambivalence, and one experience of the father as exclusive parent is an awareness of the extremes of love and frustration with the child. The "maternalization" of the father creates a new psychological experience for both parent and child. The father also achieves a kind of indestructibility as an object. There is less risk of postdivorce withdrawal by the father and of his gradual exclusion from the child's life. Even when the mother is hostile to the father, his loving, caring, and limit-setting involvement with the child prevents his becoming a shadowy figure who may be fantasized about but not experienced fully. Children who have lived part-time with their fathers and have been cared for by them directly cannot fail to identify with the father's real characteristics and understand them better.

IMPLICATIONS FOR CLINICAL PRACTICE

It is important that psychiatrists recognize the potential of early separation and divorce in facilitating father-child attachments. People who otherwise might not consult psychiatrists and psychiatric social workers do so in the face of deteriorating and possibly lost marriages. Psychiatrists, like anyone else, are subject to time-honored prejudices that are viewed as facts. Many do not believe in divorce and assert that it is always detrimental to the children. Of course, many situations deviate from the ideal described in this paper, but it is useful for psychiatrists to have a guideline for these positive effects of separation and divorce. It is obvious that if separation and divorce lead to the father's abandoning the family—literally or figuratively—detrimental effects are far more likely. By stressing the positive effect of attachment-bonding for the father, one can emphasize the inadequacy of stereotypic thinking about human experience.

It is undeniable that divorce can cause hardship for children and parents, but this is not inevitable. In clinical practice it will increasingly become psychiatrists' responsibility to help divorced (or separated) men and women to cope with their new status. Recognition of the father's potential as an adequate caretaker is essential for the helping person. In addition, it is often necessary that the mother be given the opportunity to recognize, over time, the father's importance to the children. Even reasonably healthy women tend to underestimate the importance of fathers as nurturing figures. Fathers are often viewed as providers, as performers of chores, or as representatives of authority and the "real world." In the optimum postdivorce situation the mother has increasing and regular opportunities to see the child's importance to the father and the father's importance to the child. All but the most retaliatory and sadistic women will learn to view the father as a positive factor in the child's life.

Professionals who treat separated or divorced fathers need to recognize the importance of supporting the father's continued interest in and interaction with his children. In particular, men should be helped to recognize and feel comfortable with their so-called maternal or feminine side. To achieve this, it is essential that periods of visitation or shared custody be adequate for the child and the father to achieve a true attachment to each other. This assertion is contrary to the position of Goldstein and associates (11), which advocates the need for an intense attachment to only one parent. Those authors believe that the minimization of conflict between parents takes precedence over all else.

A shared basic attachment enables a child to identify with and introject parental qualities from the father as well as the mother. The loss to children whose fathers are excluded from the developmental matrix cannot be assessed only in terms of a narcissistic injury leading to depression in the child. The loss of introjected standards, qualities, and characteristics is of equal importance. Psychoanalysts have been slow in recognizing the significance of social change and social role modification as positive factors. There has been a marked tendency to suspect the worst in terms of outcome and in terms of the unconscious motivations of the male parent who wants to truly care for his offspring.

We must ask ourselves whether the concept of role confusion is not based on sexist assumptions. The differences between mothers and fathers that are significant to children are not related to the kind of work, taste, sensibilities, or dress that either possesses: they are genital differences, which a child must come to appreciate and integrate. An in-depth approach to development should lead to the conclusion that superficial interests or activities do not determine gender identity.

This paper has stressed the potential positive effect of separate caring experiences for fathers. It should be added that truly shared caretaking in intact homes also is likely to strengthen the father-child bond and aid the development of a separate relationship, thus improving adjustment for all of those involved in the process.

Urinary MHPG and Clinical Response to Amitriptyline in Depressed Patients

BY DUANE G. SPIKER, M.D., DAVID EDWARDS, PH.D., ISRAEL HANIN, PH.D., JOHN F. NEIL, M.D., AND DAVID J. KUPFER, M.D.

The authors treated 18 rigorously diagnosed depressed patients with amitriptyline after baseline urine samples were collected for the measurement of 3-methoxy-4-hydroxyphenylglycol (MHPG). Neither age nor severity of depression before treatment correlated with MHPG excretion. There was also no significant correlation between baseline MHPG excretion and clinical response at the end of at least 25 days' treatment with amitriptyline. The authors discuss the relevance of amitriptyline and nortriptyline plasma levels to MHPG and the noradrenergic/serotonergic theories of depression.

In recent years several different attempts have been made to develop laboratory tests that might predict the response of depressed patients to various tricyclic antidepressants. One approach has been to measure urinary excretion of 3-methoxy-4-hydroxyphenylglycol (MHPG). MHPG is believed to be the principal metabolite of central nervous system norepinephrine (1, 2). It was originally studied to test the hypothesis that depression in humans is associated with a deficiency of catecholamines in the CNS (3, 4). Subsequent investigators used MHPG levels to differentiate subtypes of depression (2, 5, 6). Further investigation suggested that the excretion of MHPG might predict the response of depressed patients to different antidepressants (7–12).

In 1972 Maas and associates (7) reported on the relationship between urinary MHPG and response to two different antidepressants. In the first group of 12 patients treated with either imipramine or desmethylimipramine, the group of responders excreted smaller amounts of MHPG than did the group of nonresponders. These findings were replicated in a second series of 16 patients who were all treated with imipramine. In 1974 Maas and associates (8) summarized these data and noted that 8 of 8 depressed female patients with MHPG excretion of less than 1000 μg/24 hours responded to imipramine or desmethylimipramine. In 1975 Beckmann and Goodwin (9) replicated this work using 23 unipolar patients treated with imipramine. They reported that 9 "unequivocal responders" to imipramine had significantly lower MHPG excretion than 7 "unequivocal nonresponders" and that there was no overlap between the two groups. Although these data are impressive, there is one small study with contradictory results. Shopsin and associates (10) reported that 3 depressed women who had urinary MHPG values within the normal range nevertheless responded to imipramine. The reason for this discrepancy is unclear.

The relationship between MHPG excretion and response to amitriptyline has not been as extensively studied. In 1973 Schildkraut (11) reported that of 6 patients treated with amitriptyline, the 3 with the lowest MHPG values failed to respond to the drug, while the 3 patients with the highest values did respond. However, the 2 patients with the lowest values were diagnosed as bipolar. This confounds the results because bipolar depressed patients have consistently been found to have low MHPG excretion (2, 5, 6). In 1975 Beckmann and Goodwin (9) avoided this criticism by reporting results from a group of 16 unipolar patients treated with amitriptyline. They described 4 subjects who were "unequivocal responders" to amitriptyline and 4 who were "unequivocal nonresponders." The responders excreted significantly higher amounts of MHPG than did the nonresponders, and there was no overlap between the two groups. Sacchetti and associates (12) reported that 4 of 5 unipolar men, including 2 with very low MHPG values, responded to amitriptyline. Thus, the relationship between MHPG excretion and response to amitriptyline is less clear than that between MHPG excretion and imipramine.

Based on the above findings and other work, it has been proposed that there may be two biochemically definable types of depression, which have been called Group A and Group B (13, 14). Group A patients are characterized by low pretreatment MHPG excretion, a

favorable response to imipramine or desmethylimipramine, an elevation in mood after a trial with dextroamphetamine, and a failure to respond to amitriptyline. Based on these observations, Maas has suggested that Group A patients have a depression associated with an alteration in the noradrenergic system. Group B patients are characterized by normal to high pretreatment urinary excretion of MHPG, a favorable response to amitriptyline, a lack of mood change during a trial with dextroamphetamine, and a failure to respond to imipramine. Maas has proposed that Group B patients have an abnormality associated with the serotonergic system (14). However, as he noted, there is at least one potential flaw in this method of classification. Although amitriptyline is probably not an effective blocker of norepinephrine uptake, its metabolite nortriptyline is (14). Consequently, patients who have low pretreatment MHPG excretion and thus presumably have a depression associated with a deficiency of the noradrenergic system should be nonresponders to amitriptyline unless their plasma nortriptyline level is in the therapeutic range. If their nortriptyline level falls within the therapeutic range, they should be responders. To the best of our knowledge, no one has attempted to test the noradrenergic/serotonergic theories of depression in this manner.

The first purpose of this study, therefore, was to attempt to replicate earlier studies which suggested that high baseline urinary excretion of MHPG predicted a favorable response to amitriptyline. The second purpose was to test the noradrenergic/serotonergic theories of depression by measuring plasma nortriptyline levels in patients who had low MHPG excretion and had received an adequate trial of nortriptyline.

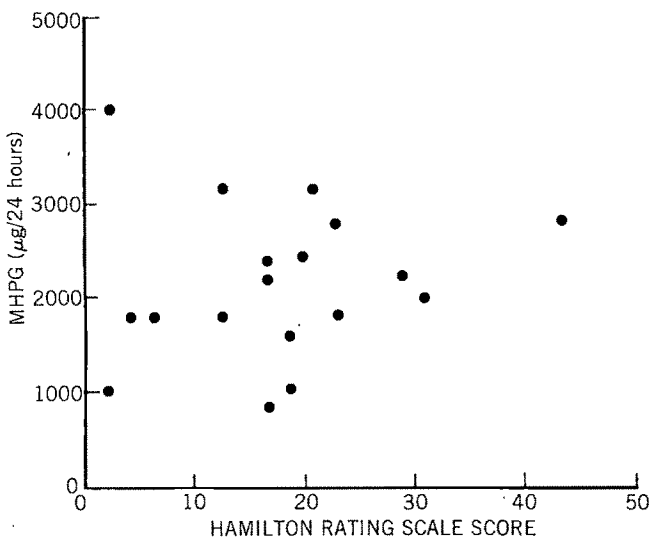
METHOD

All subjects were inpatients on the clinical research unit at Western Psychiatric Institute and Clinic. At the time of admission patients were given a traditional psychiatric interview and a complete physical examination. During the subsequent 2-week drug-free period, they underwent a variety of routine laboratory tests including thyroid function tests, an EEG, and any other tests indicated based on their history and physical examination. Any patient who was found to have a medical illness affecting the CNS was excluded from the study. All patients gave informed consent.

At the end of the 2-week drug-free period, the Schedule for Affective Disorders and Schizophrenia (SADS) (15) was completed using information from the initial interview, case records, collateral information from relatives, observation on the University of Pittsburgh and Western Psychiatric Institute and Clinic Clinical Research Unit, and a second interview with each patient. The SADS is a structured research interview that collects information necessary to make diagnoses using the Research Diagnostic Criteria (RDC) (16). For inclusion in the study the patients had to meet the RDC for major depressive disorder, primary, unipolar, and endogenous subtypes. In addition, they could not meet the criteria for the psychotic subtype. The severity of depression was measured by the Hamilton Rating Scale (HRS), using the sum of two raters on the 17-item HRS (17). Patients entered the study if the combined HRS score for two raters was 28 or more. They were subsequently rated twice weekly using the HRS. The patients were then given placebo tablets four times a day for 5–7 days. Amitriptyline was gradually substituted for the placebo tablets until the daily dose reached 200 mg per day. All patients received amitriptyline for a minimum of 25 days of treatment, and for at least the last 14 days they received 200 mg per day.

During the placebo period, at least two 24-hour urine samples were collected and aliquots were frozen at −20° C. MHPG was subsequently measured using the methods of Dekirmenjian and Maas (18). Creatinine was measured using an automated method based on the Folin and Wu procedure (19). Urine collections were considered complete only if the 24-hour creatinine excretion exceeded 1400 mg or 20 mg/kg for men and 1000 mg or 15 mg/kg for women. These values were chosen because they were approximately one standard deviation below the mean values reported in several studies (20–22). Theoretically, these values would exclude only approximately 16% of the urine samples which were in fact complete. This was considered a reasonable rate to accept to ensure that the MHPG values were not skewed downward by the inclusion of incomplete collections. Blood collection and preparation for measurement of plasma levels of amitriptyline and nortriptyline were done as previously described (23). Levels of significance were determined using Pearson's product-moment correlation (24).

RESULTS



Eighteen patients (5 men and 13 women) had at least two complete 24-hour urine collections during the drug-free period and received an adequate trial of amitriptyline. Their data are shown in table 1. The MHPG values ranged from 725 to 3906 μg/day (mean ±SD=2148±822 μg/day). There was no significant correlation between age and MHPG excretion (r=.09) or between Hamilton scores before treatment with amitriptyline levels and MHPG excretion (r=.10). The baseline MHPG values were plotted against the final Hamilton scores in figure 1. No significant correlation was observed between MHPG and final Hamilton scores (r=.10). There was also no significant correlation between MHPG excretion/creatinine excretion and final Hamilton scores (r=.01). There were 6 clear-cut amitriptyline responders (final Hamilton score of

[a]Values were obtained at the end of 25 days of treatment with amitriptyline.

FIGURE 1
Baseline MHPG Values and the Final Hamilton Rating Scale Score for 18 Depressed Patients

12 or less), and the MHPG excretion (mean±SD) in these patients was 2253±1065 μg/day. There were also 6 clear-cut nonresponders (final Hamilton score of 20 or more), and the mean MHPG excretion in this group was 2460±541 μg/day.

Table 1 shows the plasma amitriptyline levels at the end of 25 days of treatment with amitriptyline. The plasma level of amitriptyline that is effective to block the serotonergic system is unknown. However, if patients with a normal or high MHPG excretion have a depression associated with the serotonergic system, one would expect some correlation between plasma amitriptyline level and final Hamilton score. Normal MHPG excretion is approximately 1400–1600 μg/day (25–29). In the present study 14 patients had MHPG excretion greater than 1600 μg/day; their plasma amitriptyline levels were determined. There was no significant correlation between final Hamilton scores and plasma amitriptyline levels (r=.15). This correlation would not be significant even if only the 8 patients with MHPG excretion greater than 2000 μg/day (and with plasma amitriptyline levels determined) were evaluated (r=−.45).

Table 1 also shows the plasma nortriptyline levels after 25 days of treatment with amitriptyline. Of the 3 patients with low MHPG values, 2 had plasma nortriptyline levels between 50 and 150 ng/ml. One patient was a clear-cut responder and one was a partial responder (final Hamilton score of less than 20 but more than 12). One patient had a nortriptyline plasma level of 202 ng/ml and was a partial responder.

DISCUSSION

The major purpose of this study was to test the hypothesis that high baseline urinary excretion of MHPG correlates with a favorable response to amitriptyline. Our data do not support this hypothesis. Of the 6 patients in our sample with the highest MHPG values, only 2 responded to amitriptyline. In the whole sample of 18 patients, there was no correlation between baseline MHPG excretion and final Hamilton score. Correcting the data for the daily creatinine excretion did not improve the correlation. A comparison of the unequivocal responders (final Hamilton score of 12 or less) and the unequivocal nonresponders (final Hamilton score of 20 or more) also was not helpful. In fact,

the responders had a lower mean excretion of MHPG than did the nonresponders, although the difference was not statistically significant. The data were also examined using several other statistical approaches, with nonsignificant results.

The reasons for our not finding a correlation between MHPG excretion and response to amitriptyline are not clear. Diagnostically, our patients were well defined and relatively homogeneous. Our criteria for excluding urine samples because they may have been incomplete were more stringent than those of most other studies. This probably explains why the patients' mean MHPG excretion was comparatively high. One possible explanation is that in spite of adequate oral doses, some of the patients did not receive enough amitriptyline. However, the measurement of amitriptyline plasma levels allowed us to control for this variable, and that did not explain the lack of correlation. In addition, the majority of our subjects were routine admissions from the emergency room, and only 4 had had a reasonable prior trial of amitriptyline (patients 12, 13, 14, and 16). Consequently, most of our patients represented fairly typical cases of depression. At any rate, on the basis of our data, one must conclude that there are patients with normal or high baseline MHPG excretion who fail to respond to amitriptyline in spite of an adequate trial.

The interpretation of our data regarding plasma nortriptyline levels, baseline MHPG excretion, and response to amitriptyline in the context of the proposed noradrenergic/serotonergic theories of depression is less conclusive because only 3 of our patients had low MHPG excretion. One hypothesis relevant to this study is that depressed patients who excrete low baseline MHPG may have a depression associated with a deficiency of CNS norepinephrine. Although amitriptyline is not an effective blocker of the reuptake of norepinephrine, nortriptyline is. Consequently, patients who excrete low baseline MHPG should not respond to amitriptyline unless their plasma nortriptyline level is within the therapeutic range (14). Although there is some question about the upper limits, a reasonable estimate of this range is 50–150 ng/ml (30–33). Of the 3 patients in our study with low MHPG values, 2 had nortriptyline values within this range (see table 1). As noted previously, one of those was a responder and the other a partial responder. Sacchetti and associates (12) have also reported on patients with low MHPG excretion who responded to amitriptyline. In a sample of 5 subjects, 3 had low MHPG excretion and 2 of these 3 responded to amitriptyline. Sacchetti and associates' data could be used as an argument against the noradrenergic theory of depression. However, our data suggest that this apparent discrepancy may be explained by the noradrenergic blocking effect of nortriptyline. Further study in this area is indicated, and obviously plasma tricyclic antidepressant levels should be measured.

The Physical Examination in Office Practice

BY WILLIAM H. ANDERSON, M.D.

Physical illness may first declare itself as a disturbance in thinking, mood, or behavior. Recognition of physical disorders is enhanced by informed use of the relevant procedures of physical examination. Objections to physical examination are based on the assumptions that it is overly time-consuming, is psychotherapeutically contraindicated, or requires unusual skill, but observation and minimally intrusive procedures can provide much information that may exclude emergent organic conditions. Different patients, illnesses, and settings require different levels of examination; the author describes the appropriate procedure for psychotic patients, substance abusers, patients taking psychotropic medications, and other patients.

Convincing evidence now exists that physical illness may first assert itself as a disturbance in thinking, mood, or behavior (1–3). Early recognition of such conditions is imperative in order that effective treatment begin before complications supervene. As hyperspecialty medicine continues to be a predominant mode of care delivery, the psychiatrist is called on to recognize and sometimes to treat these conditions. It is possible that the internist may not have special skill in this area and may ascribe such disturbances to psychological causes.

The physical examination supplies data for the logical process of differential diagnosis. It is a procedure that must be congruent with the clinical situation. The diagnostic process generates hypotheses from the patient's history (4), attempts to support these hypotheses by observation, examination, and laboratory findings, and orders the winnowed hypotheses according to the extent of critical need for action (5). Of the plausible diagnostic hypotheses, the one that leads to a specific effective treatment should be entertained first.

When we replace the concept of physical examination as ritual with the concept of hypothesis confirmation, the usual objections to such procedures can be seen in perspective. All patients thus require a "physical examination," but the specific content must be a variable set of procedures that depend on the clinical context. If we are told by another physician that "the physical examination is negative" for a psychotic patient, this is not highly informative, as we are unaware of the physician's opinion as to which observations are relevant to the differential diagnostic questions involved. If we are told that the temperature is 37° C, the pulse is 84, the pupils are equal and reactive at 3 mm and there is no diaphoresis, we have some useful information which helps us to rank our diagnostic hypotheses in a rational order of plausibility.

The general problem, therefore, is to erect a hierarchy of examination techniques that identify serious conditions when present and yet do not subject the patient to an involved ritual of low-yield procedures. This may be accomplished by having one physical examination procedure for psychotic patients, one for possible substance abusers, one for those taking psychotropic medications, and one for all others. I will consider each of these groups separately.

Five reasons have been advanced for psychiatrists' avoidance of physical examinations (6–7). Most of these have grown out of the implicit assumption that the physical examination is a single standard procedure. To the contrary, since its purpose is to confirm or refute specific diagnostic hypotheses generated by the patient's history, the proper physical examination ought to have different areas of emphasis depending on the illness and situation. It will surprise no one that a cardiologist and an ophthalmologist will have greatly different skills, yet each is capable of performing the relevant areas of a physical evaluation. In the case of the psychiatrist, the relevant skills include the mental status examination and all other procedures and observations that discriminate between organic brain syndromes and functional conditions.

OBJECTIONS TO PHYSICAL EXAMINATIONS

1. Other physicians have greater skill in performing physical examinations. Surely the cardiologist is more astute at detecting heart murmurs, but this skill is not pertinent to the psychiatrist's task. No physician will have more skill than the psychiatrist at taking the

blood pressure, pulse, or temperature, noting movement disorders, or observing signs of autonomic dysfunction. It is likely that an internist will have less skill in certain of these critical areas than the psychiatrist, who sees many more patients who have subtle extrapyramidal and autonomic disturbances secondary to treatment with psychotropic drugs.

2. It is impractical in office practice to have the patient disrobe. This is true, yet for the relevant observations and procedures disrobing is most often unnecessary.

3. The physical examination gives a low yield of positive findings. The truth or falsity of this statement depends on the patient and circumstances. For the healthy outpatient it is usually true, but for an elderly psychotic patient in the emergency room it is usually false.

4. The performance of a physical examination poses unmanageable transference and countertransference problems. If this formulation is ever true, it applies only to those patients and psychiatrists who are currently involved together in psychoanalytic psychotherapy. This is a subset of psychiatric intervention for which diagnosis is not pertinent.

5. Performing a physical examination would expose the psychiatrist to risk of malpractice litigation. Surely the reverse is true. To look for a significant abnormality and not find it is clearly more defensible than to avoid looking altogether. As physicians responsible for the patient's care, we are obligated to have direct knowledge of those physical findings which are related to the disturbance at hand.

PHYSICAL EXAMINATION FOR COMMON TYPES OF PATIENTS

Psychotic Patients

Patients with psychosis, especially in its acute forms, require that careful attention be paid to certain physical findings in order to exclude the variety of medical conditions which may resemble manic-depressive disease or schizophrenia. Careful history and laboratory examination are also invaluable and are discussed elsewhere (8).

The relevant aspects of physical examination for psychotic patients are neither intrusive nor time-consuming. Most often they can be accomplished by the clinician's deft, firm, and gentle manner. Examination can usually take place without resorting to antipsychotic drugs before diagnosis; for very agitated patients this ideal is not always practical. In such cases a small dose of high-potency antipsychotic drug (e.g., 5 mg of haloperidol) may be injected to facilitate the examination.

There are many possible medical causes of a psychotic syndrome (9). In office practice it is generally not practical to exclude them all. It is therefore necessary to order the index of suspicion such that the most serious possible causes are considered first. Fortunately these are few in number and most often discernible by brief examination:

1. Infectious diseases. In cases of meningitis and encephalitis fever, headache, and pain on neck flexion are important to identify. Systemic infections such as subacute bacterial endocarditis cause fever and tachycardia.

2. Toxic conditions. Poisoning by tricyclic antidepressants or other anticholinergic agents may be recognized by tachycardia, fixed dilated pupils, flushed dry skin, and diminished bowel sounds. Delirium tremens (sedative withdrawal syndrome) is characterized by tremor, hyperreflexia, diaphoresis, fever, mydriasis, and tachycardia.

3. Metabolic and endocrine disorders. Hypoglycemia is suggested by diaphoresis and tachycardia, especially in an insulin-dependent diabetic. Cerebral hypoxia is suggested by history of cardiopulmonary disease with changes in vital signs. Wernicke's encephalopathy may be recognized by confusion, nystagmus, ataxia, and ophthalmoplegia. Thyrotoxicosis is suggested by enlarged thyroid, tachycardia exophthalmus, and diaphoresis.

4. Vascular conditions. Intracranial hemorrhage is suggested by sudden onset of headache with nuchal rigidity. Hypertensive encephalopathy is excluded by a relatively normal blood pressure.

While this is not an exhaustive list of the organic brain syndromes that may mimic functional psychosis, it contains most of those conditions which may cause death or serious impairment in a very short time. The principal physical findings do not require excessive manipulation or more than usual experience and dexterity.

In summary, the initial physical examination of the psychotic patient should include at least the following: 1) vital signs, especially temperature; 2) general appearance—whether the patient is neatly dressed, which would suggest very acute onset; 3) head—any signs of injury; 4) eyes—pupil size and dynamics, presence of nystagmus or exophthalmus; 5) neck—rigidity or thyroid enlargement; 6) skin color and perspiration level; 7) hands—presence of tremor, asterixis, or chorea; 8) reflexes—whether they are hyperactive or asymmetrical and whether the suck, snout, and grasp reflexes are present.

Possible Substance Abusers

Patients who may have high risk of substance abuse because of history or demographic factors require a special set of observations. Findings may differ depending on the drugs in question and whether the current state is one of intoxication or withdrawal.

Visible signs of opiate use include miosis and a smiling, sleepy appearance. Needle marks are generally concealed by clothing. Signs of withdrawal include

mydriasis, diaphoresis, gooseflesh, yawning, lacrimation, and rhinorrhoea.

Amphetamine, cocaine, and methylphenidate intoxication may cause diaphoresis, tachycardia, and elevated blood pressure. The patient is alert or even hypervigilant. The pupils are dilated and reactive to light. After abrupt withdrawal, lethargy and depression may occur. Drugs of the cannabis type produce tachycardia and reddened conjunctivae. Phencyclidine intoxication produces ataxia and nystagmus (10).

Acute intoxication from alcohol, barbiturates, or related sedative-hypnotics causes ataxia, slurred speech, and nystagmus. Chronic use of alcohol may sometimes produce facial erythema and edema or hoarseness. Early or mild withdrawal signs include tremor and diaphoresis. Later and more severe signs of withdrawal are tachycardia, mydriasis, hyperreflexia, and fever.

Atropine, scopolamine, and related drugs are occasionally abused. More frequently, patients develop anticholinergic toxicity from prescribed antipsychotics, antidepressants, and antiparkinson drugs. Recognition of these signs is described below.

Thus, the initial examination for the substance abuser should include at least the following: 1) vital signs; 2) general appearance—ataxic gait, slurred speech, or hoarseness; 3) skin—degree of moistness, presence of flushing, gooseflesh, or needlemarks; 4) eyes—pupil size and reactivity and presence of nystagmus or red or jaundiced sclera.

Patients Taking Psychotropic Medications

Adverse effects of psychotropic drugs depend on the pharmacologic class of drug and the clinical time frame. Some of those which arise in the initial weeks of treatment are recognized by history rather than physical findings. Examples are blood dyscrasias, liver disease, and allergic phenomena, which are serious but will not be considered here. I will examine only those conditions which are best identified by observation.

Antipsychotic drugs. Observable adverse effects are best considered as early (occurring in the first 10 weeks of treatment) and late (occurring months or years after treatment begins). Early observable effects consist of the Parkinson spectrum of movement disorders and anticholinergic effects.

The Parkinson syndrome spectrum consists of akinesia (which may be mistaken for depression or the flat affect of schizophrenia [11]), dystonia (sometimes mistaken for hysteria), akathisia (sometimes thought to be anxiety or psychotic agitation), and pill-rolling tremor. During the early weeks of antipsychotic treatment these effects should be anticipated and, if necessary, treated by dosage reduction or antiparkinson medication. Cogwheel rigidity is frequently discernible in the wrist joints even when other manifestations of the syndrome are minimal.

Anticholinergic action is characteristic of all antipsychotic drugs but is most pronounced in the lower potency ones such as chlorpromazine and thioridazine. Observable anticholinergic effects include tachycardia, mydriasis, fever, and diminished bowel sounds. Mental status changes, including psychosis, may occur as well. It is essential to recognize this possibility lest the anticholinergic psychosis be treated with a higher dose of antipsychotic drug, which would exacerbate the condition.

Later observable effects of antipsychotic drugs include tardive dyskinesias and skin and eye changes. The first signs of tardive dyskinesia are usually seen in the tongue, lips, and fingers. The essential feature of these abnormal movements is randomness. The tongue cannot be protruded steadily for a period of more than a few seconds. Fine vermicular movements may be seen within it. The lips may smack and pucker at random. The fourth and fifth fingers may flicker involuntarily.

Peculiarities of skin pigmentation may occasionally be seen. These are usually gray to violet, more marked in areas exposed to the sun, and frequently reversible.

Deposits of particulate matter may occasionally be seen in the cornea and lens of the eye. These are frequently reversible and may not substantially interfere with visual acuity. Thioridazine in doses above 800 mg per day has been reported to cause nonreversible and visually damaging pigmentary retinopathy.

Tricyclic antidepressants. The chief observable adverse effects of these drugs are anticholinergic, as described above, and orthostatic hypotension.

Antianxiety agents. Signs of intoxication include sedation, slurred speech, and ataxia. Signs of withdrawal may be tremor, diaphoresis, and tachycardia.

Lithium carbonate. Patients receiving this drug may be seen to have neuromuscular disturbances even at normally therapeutic levels, although generally they are seen when the lithium concentration in the blood is above usual. The major finding is essential tremor, which may be seen in the outstretched fingers and heard as a quavering of the voice. As lithium is an antithyroid drug, occasionally a euthyroid or hypothyroid goiter develops. Periodic palpation of the gland is therefore indicated.

The physical examination for patients taking psychotropic medication should thus include the following: 1) vital signs; 2) skin—moist versus dry, unusual pigment; 3) eyes—papillary dynamics, visual acuity, color of sclera, opacities of cornea and lens; 4) neck—thyroid enlargement; 5) neurological functioning: Parkinson's syndrome—akinesia, akathisia, tremor, cogwheel rigidity, and gait; tardive dyskinesia—tongue, lips, fingers; and essential tremor.

All Other Patients

In the usual office practice the typical patient on his or her first visit will not fall into the above three cate-

gories. The history will exclude many diagnostic entities that may coexist with psychiatric complaints. If there are subjective physical complaints the patient may reasonably be instructed to have these investigated by a general internist. Here the physical examination should consist mainly of a mental status examination and observation and should involve minimal procedures.

The general observations should include checking skin color for suggestions of pallor or jaundice. (For patients with marked pigmentation, their palpebral conjunctivae may be checked.) The quality of the voice may raise the possibility of hypothyroidism (a deep croak) or chronic alcoholism (hoarseness). The patient's gait and hand movements may suggest the presence of tremor or chorea. The hands may show clubbing of the fingers (suggestive of cardiopulmonary or gastrointestinal disease) or edema. The proper procedures include a handshake to judge the amount of sweating; diaphoresis might imply anxiety, hyperthyroidism, or sedative withdrawal. Taking the pulse is hardly an intrusive procedure and may yield information concerning arrhythmia or autonomic function. Blood pressure might also be checked, not because hypertension is typically associated with psychiatric manifestations, but rather as a simple check for a very prevalent and damaging treatable disease. If any of these observations suggests abnormality the psychiatrist might order laboratory tests or make a referral as appropriate.

The patient who is not psychotic, a substance abuser, or a taker of psychotropic medications may nevertheless benefit from any of the above observations but especially from having his or her pulse taken and from observation of his or her general appearance, e.g., grooming, cleanliness, appropriate dress, unusual odors, voice, skin, hair, hands (clubbing, edema, sweating).

The Neurological Examination

Whenever a psychiatric patient gives a history suggestive of neurological impairment, a detailed examination is warranted. The complexity and subtlety of such an examination may tend to discourage the psychiatrist. Nevertheless, it is important to be aware that some neurological examination procedures are especially useful. While not a substitute for a full examination by a neurologist under ideal conditions, the following procedures are included here because of their relative simplicity and high yield in terms of likelihood of discovery of pertinent findings:

Mental status. Defects of recent memory, orientation, and fund of information suggest organicity. Tactile hallucinations suggest toxic or metabolic encephalopathy, delirium tremens, or temporal lobe epilepsy.

Cranial nerves. Tests of the olfactory and optic nerves are the most useful.

Motor system. Weakness may be roughly assessed by looking for drift of outstretched arms with the eyes closed.

Sensory examination. The most useful procedures are double simultaneous stimulation, stereognosis, and stereographia.

Cerebellum. Nystagmus and past pointing tests may be useful.

Reflexes. Increased deep tendon reflexes suggest upper motor lesions and alcohol and sedative withdrawal. Useful pathologic reflexes are grasp, palmomental, suck, and glabellar tap.

COMMENT

Generally it is the patient with acute psychotic illness who most requires evaluation by the set of procedures described in this article. Even in the case of psychosis the relevant data may be obtained with observations and procedures that are only minimally intrusive. Of course, all psychiatric patients deserve and require careful medical screening. Those who are psychotic, those who may be substance abusers, and those taking psychotropic medication may especially benefit from early recognition of medical conditions. All patients should have whatever screening is clinically indicated in the opinion of the psychiatrist or the patient's general physician. The procedures described here are not intended to replace the general physical and neurological examination properly used on admission to an inpatient service. Instead, this method is useful for early identification of serious medical illness that may initially declare itself as behavioral change. Such patients often enter the health care system through a psychiatrist's office or by psychiatric consultation in the emergency department. Psychiatrists must be justly confident of their capacity to recognize medical illness that causes or coexists with the disturbances of thinking, feeling, and acting, which are our professional concern. The relevant physical examination is an essential tool for the accomplishment of this purpose.

The Manfred S. Guttmacher Award

The American Psychiatric Association invites applications for its biennial Manfred S. Guttmacher Award for 1981. The award is now given in odd-numbered years for outstanding contribution to the literature of forensic psychiatry in the form of a book, monograph, paper, or other work, including audio-visual presentations (films, etc.), submitted to or presented at any professional meeting or published during the period from December 1, 1978, to December 1, 1980. A plaque and an honorarium of $750 will be presented to the award recipient at the Convocation of Fellows at the 1981 APA annual meeting. Please note that the award recipient is now required to give a lecture at the annual meeting.

Anyone who wishes may apply by submitting five copies of the work as well as five abstracts to Robert L. Sadoff, M.D., Chairperson, Guttmacher Award Board, 1700 Eighteenth Street, N.W., Washington, D.C. 20009. Entries will be acknowledged but will not be returned.

Entries received by December 1, 1980, will be considered.

The Phenomenology of Near-Death Experiences

BY BRUCE GREYSON, M.D., AND IAN STEVENSON, M.D.

The authors studied retrospectively 78 reports of "near-death experiences" using subjects' narratives and questionnaires, interviews, and medical records. Prior experiences suggestive of transcendence of death were more common among these subjects than among control populations, but prior experiences suggestive of extrasensory phenomena were less common. Subsequent changes in attitudes were more common than among subjects in other studies who had had psychic experiences. The influence of cultural and psychological factors, sensory deprivation, and reflex adaptive responses to stress explain some but not all of the features of near-death experiences. Their potential value to our conceptualization of dying and to suicide prevention and the care of the terminally ill justifies further investigation.

Profound subjective events experienced on the threshold of death, so-called "near-death experiences," have been reported by people who have been seriously injured or ill but unexpectedly recovered and by people who had anticipated imminent death in potentially fatal situations but escaped uninjured (1). The investigation of near-death experiences may contribute not only to our understanding of the dying process but to our care of terminally ill patients, our ability to help grieving families, and our approach to suicidal patients. In this paper we describe the characteristic features of a large self-selected sample of people who had had near-death experiences and discuss the implications of these data for the interpretation of such phenomena.

Received Oct. 9, 1979; accepted Feb. 15, 1980.

METHOD

We retrospectively collected 78 reports of near-death experiences from three self-selected sources: letters to a national magazine from correspondents who had read an article on near-death experiences (18 cases), responses to announcements of our interest in studying such cases in professional newsletters and in magazines that specialize in popular articles about parapsychological phenomena (22 cases), and communications from informants who knew of the long-standing interest of one of us (I.S.) in the nature of death (38 cases).

For each case we obtained a firsthand written or tape-recorded narrative account from the person reporting the experience and supplemented these accounts whenever possible by a detailed questionnaire, personal interview, and examination of medical records relevant to the close brush with death.

We transferred characteristics of each respondent's reported near-death experience to a checklist, either directly from questionnaire responses (38 cases) or by extracting such data as were available from the narrative report, interview, and medical records of those respondents who did not complete the questionnaire (40 cases). Frequencies of individual items were then computed, and certain cross-tabulations, selected for their relevance to explanatory hypotheses were evaluated by chi-square tests.

RESULTS

Predisposing and Precipitating Factors

At the time of the near-death experience 27% of our respondents were 18 years old or younger, 32% were 19 to 35 years old, and 40% were older than 35 years. All of our subjects were Caucasian; 63% were women. At the time of the near-death experience 47% were married, 40% were single, 6% were separated or divorced, and 6% were widowed.

At the time of the study 76% had completed high school, and 53% had attended college. Our respondents included executives and professionals (25%), service workers and laborers (29%), and students and housewives (31%). Fifty-eight percent of our sample were Protestant, 18% Catholic, 4% adherents to Eastern faiths, 8% agnostics; none were Jewish or Muslim.

The incidences of apparent mystical or paranormal

TABLE 1
Mystical or Paranormal Experiences in Subjects Who Later Had Near-Death Experiences, the General Population (2), and Psychiatric Inpatients (3)

Experience	Percent of Group: Subjects with Near-Death Experiences (N=78)	General Population (N=354)	Psychiatric Inpatients (N=92)
More frequent among people with near-death experiences			
Sense of unity with nature	50	28	—
Sense of God within oneself	37		
Apparent perception of persons not present	48	17	30
Apparent memory of a previous life	43	8	—
Auras/halos sensed around others	29	5	—
"Out-of-body experiences"	27	14	19
Apparent communication with the dead	24	8	15
Less frequent among people with near-death experiences			
Apparent clairvoyance or precognition while awake	31	38	47
Apparent clairvoyant or precognitive dreams	28	36	40
Figuring in another person's apparent psychic experience	13	18	21
Seeing objects move without apparent cause	5	8	—

experiences that occurred before the near-death experience are summarized in table 1, where they are compared with data from previous surveys of the general population (2) and of psychiatric inpatients (3). In addition, 28% of our respondents reported having had a close brush with death prior to the one being investigated, and 25% acknowledged having read something about near-death experiences before having this close brush with death.

Before the near-death experience 50% of our respondents had expected dying to be painful; only 3% had expected it to be pleasant. Seventy-seven percent had expected to pass into some unearthly realm of existence after death, 63% had expected to be reunited with deceased acquaintances, 29% had expected to be reborn on earth, and 17% had some other expectation of postmortem survival; 35% had expected to cease existing at or shortly after death. Thirty-two percent stated that they either wanted to die or were ambivalent about dying at the time of the near-death experience.

Medical personnel were present during or immediately after the near-death experience in 80% of our cases. The experience was precipitated by medical illness in 40% of our cases, by traumatic injury in 37% (of which 70% were accidental), by surgical operation in 13%, by childbirth in 7%, and by drug ingestion in 4%. Forty-seven percent of the subjects reported having taken some type of drug or alcohol on the day of the experience.

Forty-one percent of our subjects reported that they had been considered dead during the near-death experience; an additional 41% reported some degree of physical injury, and 18% reported escaping the close brush with death without any injury. Thirty percent of our respondents reported that the duration of the experience was more than an hour; 67% reported that it seemed to last more than an hour.

Features of Near-Death Experiences

The impression of feeling or seeing oneself to be outside the physical body, an "out-of-the-body experience," was reported by 75% of our respondents. The apparent exit from the body was most commonly described as easy (by 96% of those reporting out-of-the-body experiences) and instantaneous (68%). In 66% of our cases the initial impression that one was out of the body was reported as due to seeing one's body as if from another point in space.

Ninety-five percent of those reporting out-of-the-body experiences stated that they seemed to move about while seemingly out of the body, most commonly within a limited area a few yards from the body (45%); 71% claimed that they could see and hear persons physically present. The apparent re-entry into the physical body was most commonly described as easy (79%) and instantaneous (71%).

The impression of having some sort of nonphysical body separate from the physical body was reported by 58% of our respondents (77% of those reporting out-of-the-body experiences). The nonphysical body was most commonly described as lighter in weight than the respondent's physical body (74%) but the same size (68%) and the same age (84%). The nonphysical body was described as showing some indication of "life" (e.g., pulse, breath) by 67% of those reporting a nonphysical body and as "linked" to the physical body in some way by 28%. Twenty percent of those reporting a nonphysical body claimed that sensorimotor or structural defects present in their physical body (e.g., partial deafness, missing limbs) were absent in the nonphysical body; 3% reported such defects to be present in the nonphysical body.

The impression of passing through a tunnel or similar structure was reported by 31% of our respondents, more frequently by executives and professionals than by laborers and service workers ($\chi^2=14.75$, df=3, $p<.01$). Seeming to enter some unearthly realm of existence was reported by 72% of our subjects, more frequently by women than by men ($\chi^2=7.58$, df=1, $p<.05$); such reports were not correlated with prior beliefs or expectations. Seeming to reach a border or "point of no return" was reported by 57% of our respondents.

Forty-nine percent of our subjects reported seeming to meet some person(s) not physically present; these

persons included a "being of light" (not otherwise identifiable) (27%), religious figures (25%), deceased acquaintances (16%), living acquaintances (14%), and unidentified strangers (26%). These apparent encounters with persons not physically present were more likely to be reported as part of a near-death experience occurring at home or outdoors than as part of one that occurred in a hospital or other public place ($\chi^2=14.95$, df=4, $p<.01$). There was no correlation between such apparent meetings and prior beliefs or expectations. Thirteen percent of our respondents reported a feeling of being judged or held accountable for their lives.

Unusual visual phenomena (e.g., lights, auras) were reported by 48% of our respondents and occurred predominantly during nighttime near-death experiences ($\chi^2=13.42$, df=2, $p<.01$). Unusual somatic sensations (e.g., warmth, analgesia) were reported by 71% of our respondents, unusual auditory phenomena (e.g., music, noises) by 57%, unusual olfactory phenomena by 25%, and unusual gustatory phenomena by 10%. There were no significant diurnal variations in reported sensations other than visual phenomena.

Distortions of the sense of time were reported by 79% of our respondents; 54% reported that time seemed to pass more slowly than usual during the near-death experience. This subjective slowing of time was inversely correlated with the use of drugs or alcohol on the day of the experience ($\chi^2=5.88$, df=2, $p<.05$) and with prior religiosity ($\chi^2=7.44$, df=2, $p<.05$).

Apparent extrasensory experiences during the near-death experiences were reported by 39% of our respondents; 21% claimed that during the experience he or she figured in another person's psychic experience. Reports of extrasensory events during a near-death experience were not correlated with the respondent's prior knowledge about parapsychological phenomena, nor with reports of prior experiences suggestive of parapsychological phenomena.

Fifty-two percent of our subjects reported having believed during the near-death experience that they were dying. This belief was inversely correlated with the subjective duration of the experience ($\chi^2=7.38$, df=2, $p<.05$); that is, the longer the experience seemed to last, the less likely the subject was to believe that he or she was indeed dying.

Review of past events, or "panoramic memory," was reported by 27% of our respondents; memories were most commonly described as appearing all at once (38%) rather than in some particular sequence.

The near-death experience was reported to have been a very positive affective experience by 15% of our respondents, mildly positive by 40%, neutral or mildly negative by 45%, and very negative by none. Positive affect was significantly correlated with distortions in one's sense of time ($\chi^2=6.89$, df=2, $p<.05$).

No single feature of the near-death experience was significantly correlated with the respondent's having had one previously or with the extent of the respondent's prior knowledge about near-death experiences.

TABLE 2
Percent of People Who Reported Changes in Attitudes After a Near-Death or Psychic Experience (2)

Subject of Attitude Change	Near-Death Experience (N=78)	Psychic Experience (N=354)
God or religion	75	23
Self	74	27
Own death	73	—
Death in general	72	13
Life and its meaning, health	64	25
Humanity	55	17
Suicide	50	—
Family, friends	50	17
Nature	45	12
Material possessions	45	9
Sex, marriage	42	16
Personal fame or power	42	5
War, murder	37	5
Education	37	6
Science	34	5
Society	29	6
Business	29	6

Sequelae

The near-death experiences reported in this study occurred 1-67 years before our investigation (median=30 years). At the time of the investigation, 60% of our respondents claimed to have detailed recollections of the experience, and 83% claimed that the memory of the near-death experience was clearer than his or her memories of other events from the same time period.

Respondents' changes in attitudes after their near-death experiences are presented in table 2, where they are compared with data on attitude changes following psychic experiences among the general population (2). Subsequent changes in attitude were more frequent among those of our respondents who believed during the experience that they were indeed dying ($\chi^2=5.17$, df=1, $p<.05$) and among those who reported panoramic memory experiences ($\chi^2=4.02$, df=1, $p<.05$) but were not correlated with any factor prior to or precipitating the near-death experience.

DISCUSSION

Because our cases were not randomly selected, the preponderance of whites, women, and single persons among our respondents may reflect sampling biases. Our subjects were characteristic of white Americans in terms of education and occupation but included a disproportionate majority of Protestants.

Our respondents as a group shared a distinct pattern of reported mystical and paranormal experiences prior to the near-death experience: they acknowledged a

higher incidence than either the general population or identified psychiatric patients of experiences that might suggest transcendence of or survival after death but a lower incidence of prior apparent extrasensory phenomena than either the general population or the sample of psychiatric patients.

The correlations in our data between occupation and seeming to enter a tunnel and between sex and seeming to enter another realm of existence suggest cultural or psychological factors influencing the perception or report of a near-death experience. Despite the absence of correlation between prior beliefs and specific features of the experience, the finding that our respondents also reported prior experiences suggesting transcendence of death more often than comparison groups further supports an influence of prior experiences on reports of near-death experiences.

Comer and associates (4) and Noyes (5) suggested that sensory deprivation may produce phenomena similar to those reported in near-death experiences. In our data, the incidence of unusual visual phenomena in near-death experiences occurring at night was higher than that during daylight hours, which may suggest the influence of decreased sensory input; this diurnal variation in unusual sensory phenomena was not reported for other sensory modalities that would not be affected by darkness. Our finding that apparent meetings with persons not physically present were reported more frequently in near-death experiences occurring in isolation (outdoors, at home) than in those occurring in public buildings may be related to the relative lack of sensory stimulation in the former settings.

Noyes and Kletti (6) suggested that the apparent separation from the physical body, the impression of time moving more slowly, and the hyperalert but narrowly focused cognitive and sensory functioning seen in near-death experiences constitute a reflex adaptive response to a life-threatening danger: potentially fatal crises may induce a focusing on accelerated internal processes, producing a comparative subjective slowing of external time and a concomitant feeling of depersonalization. The correlation in our series between positive affect during the near-death experience and distortion of one's sense of time is compatible with the hypothesis that temporal slowing acts as a defense mechanism. The inverse correlation between the impression of temporal slowing and religiosity also supports Noyes and Kletti's interpretation of near-death experiences if it is assumed that death may be perceived as more threatening by the less religious. Our finding that the subjective slowing of time was reported significantly less often by those who had taken drugs or alcohol on the day of the experience suggests that certain drug effects may impede the reflex response of internal focusing; consequently a near-death experience occurring in a drug-free individual may paradoxically diverge more from the normal state of consciousness than would a drug-inhibited near-death experience. Osis and Haraldsson (7) reported that drug intoxication during a close brush with death diminished the likelihood of a near-death experience.

The interpretation of near-death experiences as adaptive responses does not adequately explain the mystical components of these experiences (1, 6). Melges and associates (8) suggested that temporal disorganization and depersonalization, both seen in near-death experiences, may produce the mistaken impression of paranormal connections between unrelated events. Our finding that apparent extrasensory experiences during the near-death experience were not correlated either with subjective slowing of time or with reported out-of-the-body experiences does not support this hypothesis.

The reported effects of the near-death experience on the subsequent attitudes of our respondents are consistent with those reported previously (5, 6) and are far more pervasive than reported effects of other mystical or paranormal experiences in the general population. If near-death experiences are suggestive of postmortem survival, as those who report such experiences commonly claim (5–7), then their potential contribution to our understanding of death, and of the process of dying, alone justifies further investigation. On the other hand, even if near-death experiences are the epiphenomena of adaptive defense mechanisms or transient delirious states, their profound impact on subsequent attitudes justifies their further study. We suggest that further investigations of near-death experiences be conducted prospectively on patients who are at high risk for such experiences, such as a cohort of coronary care unit patients, in order to eliminate the sampling biases that have occurred in retrospective studies and the possible errors of interpretation attendant on such biases.

Nightmares: Clinical Characteristics and Personality Patterns

BY ANTHONY KALES, M.D., CONSTANTIN R. SOLDATOS, M.D., ALEX B. CALDWELL, PH.D., DENNIS S. CHARNEY, M.D., JOYCE D. KALES, M.D., DAVID MARKEL, M.D., AND ROGER CADIEUX, M.D.

The authors evaluated the development and clinical course of nightmares and the personality patterns of people with this disorder by studying 30 adults who had a current complaint of nightmares. Nightmares usually began in childhood or adolescence and were chronic. Psychological factors played a major role in the development and persistence of nightmares, major life events were often associated with the onset of the disorder, mental stress usually increased the frequency of events, and psychological testing indicated relatively high levels of psychopathology. Nightmare sufferers in general were distrustful, alienated, and emotionally estranged, and many showed a chronic schizoid pattern of adjustment, but they were not overtly psychotic.

Nightmares are nocturnal episodes of intense anxiety and fear associated with a vivid and emotionally charged dream experience. Nightmares are common in children but are not infrequent in adults; in a survey of a large metropolitan area (1), 5.3% of the adults reported a current complaint of nightmares.

The word "nightmares" traditionally has been used to refer to both actual nightmares, which are the common frightening or bad dreams, and the much less common night terrors (pavor nocturnus in children and incubus attack in adults). Nightmares occur during REM sleep (2, 3), whereas night terrors occur in slow wave sleep (stages 3 and 4) (3–5). In most cases, however, nightmares can be easily differentiated from night terrors on the basis of their general clinical characteristics. The night terror is accompanied by much more anxiety, vocalization, motility, and autonomic discharge. Also, whereas there is amnesia or very little recall of the night terror event, there typically is detailed recall of the nightmare (2–6).

Most clinical research on nightmares has focused on the content of terrifying dreams, particularly in childhood, and their psychological meaning (7–10). Thus there is little general clinical information available on this disorder in adults. The primary goals of this study were to assess the development and course of nightmares, clinical characteristics, and psychological correlates in adults, including personality patterns.

METHOD

We evaluated 30 adult subjects with a current complaint of nightmares. Their mean age was 39.1 years (range, 19–77 years); 27 were women and 3 were men. All of the subjects responded to an advertisement by our Sleep Research and Treatment Center for individuals with a current or past problem of nightmares. To qualify for the study, each subject had to have a frequency of at least 12 nightmares per year.

Each subject participated in an interview that was structured to obtain information on the clinical characteristics of his or her nightmares, and each completed the Minnesota Multiphasic Personality Inventory (MMPI) as well as a comprehensive sleep questionnaire. A subsample of 20 subjects with a current complaint of nightmares whose mean age was 39.7 years (range, 19–77) also completed a special questionnaire that provided additional dream history data, the Symptom Check List (SCL-90), and information on personal and family mental health.

The general sleep history data as well as the MMPI scores of the group of subjects with nightmares were compared with those of a group of 30 age- and sex-matched control subjects. The control subjects, who were required to have negative histories for past and current sleep disorders, were also recruited through a newspaper advertisement.

The dream data were analyzed by chi-square tests, except for the number of nights per year when dreams were recalled, which were analyzed using Student's t test. Data from the mental health history were ana-

A preliminary report of some of these data was presented at the annual meeting of the Association of the Psychophysiological Study of Sleep, Houston, Tex., April 1977. Received Aug. 13, 1979; revised Jan. 28, 1980; accepted March 11, 1980.

lyzed by chi-square tests. Individual MMPIs were considered invalid if more than 20 of the 550 questions were left unanswered, if the raw score on the F scale was higher than 22, or if both the raw score on the F scale was between 17 through 22 inclusive and the difference between the raw F minus raw K scores was more than 11. The MMPI data were analyzed in terms of absolute elevations of the individual scales, by mean elevations within groups, and by code or profile pattern types. The between-group differences in the mean scores for each of the eight major clinical MMPI scales and the averages of the number of pathologically elevated scales per individual (T score of 70 or above) were compared using Student's t test. Chi-square comparisons were made between groups as to the number of individuals with at least one pathologically elevated MMPI scale.

Finally, the raw scores for the nine symptom dimensions and the three global indices of the SCL-90 were scaled on the basis of normative data derived from a nonpatient sample of men and women (11). Comparisons between the 20 subjects with nightmares and 20 matched control subjects for the mean values of the SCL-90 were made using Student's t test. The mental health data for these groups were compared using chi-square tests. The minimum confidence level for all statistical analyses was $p<.05$.

RESULTS

The results are reported in relation to three major areas: 1) the development and clinical course of nightmares, 2) characteristics of dreams and nightmare events, and 3) personality patterns and mental health correlates of nightmare sufferers.

Development and Clinical Course of Nightmares

Half of the group of subjects with nightmares had an age of onset before age 10; two-thirds had experienced nightmares by age 20. The distribution of the age of onset by 10-year epochs was as follows: 1–10 years, 15 subjects; 11–20 years, 5; 21–30 years, 4; 31–40 years, 3; 41–50 years, 1; and 51–60 years, 2. The mean duration of this sleep disorder was 21.6 years (range, 2–50 years). The occurrence of a major life event preceding the onset of the disorder was reported by 60% of the subjects.

The peak frequency for nightmares was about 3 episodes per week; the current frequency was about 2½ episodes per week. A very high percentage of the subjects (90%) reported that mental stress increased the frequency of their episodes. One-third (33%) thought that fatigue increased the frequency of their episodes, and only a few (13%) reported that a change in sleep environment increased the frequency of their episodes.

Positive histories for other current or past sleep disorders were reported by nightmare subjects as follows: 43%, insomnia; 33%, sleeptalking; 17%, sleepwalking; 13%, enuresis; and 7%, night terrors.

Characteristics of Dreams and Nightmare Events

When comparing the general dream data of the subjects with nightmares (independent of their nightmare dreams) with the dream data of the normal control subjects, we found that the subjects with nightmares reported recall for their dreams more nights per year (181.6 versus 90.9, $p<.05$). In addition, these subjects more frequently reported that their dream recall was detailed ($p<.01$) and that their mood was affected the next day by the previous night's dreams ($p<.05$).

Nightmares did not typically occur during any one period of the night. The average time of occurrence of nightmares was 212.3 minutes after sleep onset. Five of the subjects with nightmares were unable to specify a given time of night, although they indicated that their episodes were less likely to occur early in the night. Nineteen of the remaining 25 subjects with nightmares reported a time of occurrence of their episodes that corresponded to the second and the last thirds of the night. The mean reported duration of the nightmare episodes was about 12 minutes (range, 1–25).

Typically, the subjects reported that they spontaneously awakened from their nightmares; awake time following nightmares averaged 23.2 minutes. Usually the content of the nightmare was associated with fear. Specific fears were reported by the following percentages: fear of attack, 73%; fear of falling, 73%; and fear of death, 60%. Thirty percent of the subjects with nightmares reported a feeling of choking or suffocating. Most of them (83%) reported that they often experienced recurring nightmares.

Personality Characteristics and Mental Health Correlates

Table 1 lists the mean values of the clinical MMPI scales for the subjects with nightmares and for their control group. One nightmare subject (a 35-year-old man) had an invalid MMPI and was excluded from the analysis. When compared with their controls, the subjects with nightmares had higher mean values on all eight clinical scales ($p<.01$ by Sign test) (see table 1). The group of subjects with nightmares also had at least one pathologically elevated clinical scale two and a half times as often as the normal control group (68% versus 26%, $p<.01$). The mean number of elevated scales per individual for the nightmare subjects was 2.6, versus 0.3 for the control group ($p<.01$). The subjects who had an age of onset of the nightmare disorder after age 18 had relatively higher scores on every clinical MMPI scale except for mania in comparison with the subjects who had an earlier age of onset.

The three highest mean scores for the subjects with nightmares were, from highest to lowest, for the scales of psychopathic deviate, schizophrenia, and hysteria.

TABLE 1
MMPI Findings in Subjects with Nightmares and Normal Control Subjects

MMPI Scale	Subjects with Nightmares		Normal Control Subjects	
	Mean	SE	Mean	SE
Hypochondriasis (Hs)[a]	63.0	2.1	48.5	1.4
Depression (D)[a]	63.8	2.2	49.2	1.9
Hysteria (Hy)[a]	66.2	1.8	54.0	1.7
Psychopathic deviate (Pd)[a]	69.1	2.4	55.2	1.8
Paranoia (Pa)[a]	63.4	1.8	55.2	1.2
Psychasthenia (Pt)[a]	65.3	2.4	50.3	1.4
Schizophrenia (Sc)[a]	68.8	2.7	52.8	1.7
Mania (Ma)	59.0	2.0	55.6	1.7

[a]The difference between the groups was significant by Student's t test ($p<.01$).

The complete mean profile for the subjects with nightmares coded *'48 37 261*-9. The highest percentages of subjects with nightmares having pathologically elevated scores on a given scale were 48% for psychopathic deviate, 41% for schizophrenia, and 38% for hysteria. Also, the density values for these scales were similar in terms of their being one of the three highest scales for each subject's MMPI pattern: 56.3% for psychopathic deviate, 51.1% for schizophrenia, and 46.6% for hysteria.

The psychopathic deviate and schizophrenia elements were predominant. Not only were these among the three highest scales in 56% and 51% of our profiles, respectively, but 5 of the valid 29 profiles coded 4-8 or 8-4. Subjects whose MMPIs code as 4-8/8-4 are typically described as distrustful, alienated, and estranged (12). They are quick to withdraw emotionally and to overreact to mistreatment or to what they perceive as mistreatment. They lack persistence in the pursuit of goals and repeatedly have difficulties in making the sacrifices that are necessary to maintain meaningful long-term relationships. These characteristics lead to serious difficulties, such as underachievement in school and work, repetitive sexual problems, and repeated involvement in broadly sadomasochistic and mutually destructive relationships. They often seek clinical help at times of situational stress and acute distress, especially when they have alienated the other person in their current primary relationship. When more disturbed and depressed, they may force care and intervention (and thus reassurance against their alienation) by attempting suicide.

The consistency of elevations on the schizophrenia scale in our sample suggests long-term schizoidness and perhaps what Meehl termed "schizotypy" (13). However, there was no indication of any overt psychoticism. Finally, the values for the psychopathic deviate and hysteria scales were among the three highest mean scores for the group as well as among the three highest scales in individual profiles. This indicates a potential for dissociative episodes in our sample.

The SCL-90 scores for the subjects with nightmares were significantly higher on each of the nine symptom dimensions compared with the scores for the control subjects. In addition, the scores for each of the three global indexes were significantly higher ($p<.01$) among the subjects with nightmares; general symptom index, 68.9 versus 54.1; positive symptom total, 61.4 versus 51.0; and positive symptom distress, 70.0 versus 53.4.

Analysis of the questionnaire items pertaining to personal and family mental health showed that more subjects with nightmares than control subjects reported having had emotional problems ($p<.05$) and having considered committing suicide ($p<.01$). Also, more nightmare subjects than control subjects reported emotional problems in their families ($p<.05$) and that family members had committed suicide ($p<.05$).

DISCUSSION

Clinical Course and Characteristics

Among our subjects with nightmares, the nightmares usually began in childhood or adolescence and were a chronic condition. In some cases, however, the onset was in middle life or even later. The high frequency of nightmares at the time of their peak occurrence and at the time when the subjects were evaluated suggests that the clinical course of the disorder is relatively consistent. It is possible, however, that individuals with a low nightmare frequency were less concerned and did not contact us.

Nearly all of the subjects with nightmares were women. It is unlikely that the sex ratio in our sample approximates the sex ratio of people who have nightmares. Nightmares have been reported to be slightly more frequent among women, and even this small difference has been considered a function of societal expectations: to preserve their masculine image, men would be less likely to admit to having nightmares (14). If this assumption is correct, even fewer men with nightmares would be expected to respond to an advertisement such as ours.

In relation to general dream characteristics, our nightmare sufferers in comparison with their controls reported more frequent and intense dreams; they also reported that these dreams had a greater impact on their mood the next day. Our finding of a high prevalence of other sleep disorders in our nightmare patients compared with the prevalence of these disorders in the general population (1) confirms previous observations (15-17). The relatively high prevalence of insomnia in the subjects with nightmares may reflect the sleep disruption directly caused by the nightmares and/or the psychopathology that commonly underlies both insomnia and nightmares. As for the high prevalence of sleeptalking in these subjects, this may be accounted for by the sleeptalking that often occurs during the nightmare episodes themselves.

Etiological Considerations

From a developmental standpoint, childhood nightmares are most often related to specific phases of growth: they are most common during the preschool and early school years. Mack (7) has reviewed and discussed the relationship of nightmares to ego development and to conflict. One could also postulate that neurophysiological changes related to the maturing brain contribute to the occurrence of nightmares during these stages of development.

The persistence of nightmares into adulthood in our subjects appeared to be correlated with the presence of serious psychopathology. Major life events preceded the onset of the disorder in 60% of the subjects, and mental stress increased the frequency of episodes in 90% of the subjects. In addition, the SCL-90 data show high levels of psychopathology for every symptom dimension as well as for the three global indexes. Furthermore, the MMPI data, in addition to showing that these patients had considerable psychopathology, also indicate a common personality pattern for nightmare sufferers (4-8/8-4 MMPI code types). The nightmare sufferers in general were distrustful, alienated, estranged, oversensitive-overreacting, and egocentric. Their distrustfulness, however, was diffuse and generalized, and in this context was not genuinely paranoid in terms of fixed persecutory beliefs that would be directed toward a specific object. None of the subjects was overtly psychotic, although many had an underlying chronic schizoid pattern of adjustment.

We consider morbid nightmares to be episodic releases of intense emotions in individuals with long-term schizoid adjustments and chronic difficulties in dealing with interpersonal resentments and fears of hostility from others. When the individual cannot adapt to the excessive fear and hostility resulting from conflictual and antagonistic object relations by sufficiently discharging them during the daytime, the fear and hostility may be expressed during sleep in the form of the nightmare. Thus the nightmare would serve as a vehicle not only for discharging such unreleased fears of hostility but also for extinguishing unfinished anger and generally negative emotionality. When this distressing emotionality is finally expressed in the nightmare, it becomes anxiety-provoking and produces more fear because of its punitive consequences.

The dissociative elements that were apparent in our subjects, as suggested by the elevations on the hysteria scale in combination with the psychopathic deviate scale of the MMPI, appear to have an ego-protective function by enhancing the degree to which the nightmares are experienced as ego-alien, as if the nightmares somehow came from "outside" the person. The dissociativeness of the 3-4/4-3 profile is also directed toward avoiding frightening, hostile interactions. From this perspective, the fears and hostility in the nightmares, originating from unresolved anger in everyday life, would be more acceptable if viewed as not "self-owned."

Our findings extend the results of several other investigations, including our preliminary report on nightmare sufferers (18), a subsequent brief report on adult nightmare patients (19), and a study of insomniac patients who also had nightmares (20). The correlation of nightmares and psychopathology is also in agreement with a study of psychotic patients showing that frequent nightmare sufferers demonstrated greater manifest anxiety and lower ego strength (17). Further, a significant positive correlation was found between scores on the Manifest Anxiety Scale and nightmare frequency (16). Our findings in nightmare sufferers are similar to those of Cartwright (21) in individuals with repetitive dreams, many of which were unpleasant. Specifically, she related repetitive dreams to periods of stress associated with strong affect during the day.

The subjects with nightmares were found to have an underlying "schizotypy" (13) (a chronically schizoid pattern of adjustment), but none was overtly psychotic. The high value for the MMPI schizophrenia scale in our sample is in general agreement with the finding by Hartmann and Russ (19), although their subjects scored even higher on this scale. Nevertheless, their sample had a mean age of 22 years, and it is well documented that disturbed younger people often obtain elevated scores on this scale. If, according to their contention, nightmares were a "marker for schizophrenia," one would expect the score for the schizophrenia scale in a considerably older sample of people with nightmares such as ours to be higher and to include distinctly psychotic profiles, but this was not the case. In general, their results were difficult to interpret because they did not present data on group mean profiles, percentage of primed profiles, or code type frequency. In our subjects the MMPI depression scale was not prominent, as it was in their study (19), but our subjects reported a significantly greater frequency of past suicidal ideation than did controls. The lack of elevation of the depression scale may have been due to the limited number of men in our sample because it was prominent only in the men studied by Hartmann and Russ. This is of potential clinical importance because when the depression scale is elevated in subjects showing the 4-8/8-4 code type, the risk of suicide attempt increases.

Clinical Applications

The evaluation of the patient complaining of nightmares begins with taking a thorough history, including age at onset, frequency of episodes, time of occurrence, behavior associated with the episode, length of the episode, degree of recall of mental activity, general daytime behavior and adjustment, and relation of the onset or recurrence of nightmares to stressful major life events. Since many drugs, including alcohol, may induce marked changes in both the frequency and in-

tensity of dreaming (22, 23), a complete drug history is very important.

A thorough history is almost always sufficient in differentiating between nightmares and night terrors. The night terror typically occurs early in the night and is identified by excessive vocalization and motility, a marked increase in autonomic response, impaired arousal following the event, and total amnesia or limited recall of the episode (2–6, 24). The nightmare, in contrast, may occur at any time during the night and is characterized by limited vocalization and motility, minimal autonomic response, unimpaired arousal, prolonged wakefulness after the event, and vivid, detailed recall of the episode.

In the assessment of the adult patient with nightmares, a careful psychiatric evaluation should follow the taking of the history. If there is an indication of a considerable degree of psychopathology, as was often the case with our nightmare sufferers, the nature of the intrapsychic conflicts should be explored. For example, the physician may determine that early life experiences cause greater concerns and preoccupation with death in patients with nightmares (25). Although monosymptomatic psychiatric conditions, such as chronic fears or phobias, may be responsible for nightmares, it is usually a more global psychological disturbance that causes nightmares in adulthood, as demonstrated in the present study.

Since the nightmare sufferer's emotional condition is often complicated rather than monosymptomatic, we would expect behavioral treatment (26–28) to be effective only in selected cases but insight-oriented psychotherapies more likely to be effective in the vast majority of cases. The psychotherapist should be aware of the distrustfulness and alienation often present in the nightmare sufferer and the consequent likelihood of his or her suddenly terminating treatment. Thus a major consideration at the beginning of therapy is to deal with issues of trust and develop a sound therapeutic relationship and then to help the patient achieve a better understanding of his or her emotions, particularly anger. This would enable the patient to express his or her emotions more efficiently, rather than becoming excessively frustrated and, as a consequence, discharging resentments in nightmares.

The psychotherapist should be alert to the schizoid adjustment in the nightmare sufferer's lifestyle, but he or she should understand that the patient's coping mechanisms generally are not psychotic in nature. When overtly psychotic behavior is associated with the presence of nightmares, however, the psychiatrist should proceed with the indicated antipsychotic treatment. He or she should also be alert for the presence of depression, especially in the male nightmare sufferer, since he tends to avoid professional help and thus a suicidal potential may go unnoticed.

Identification of a Subgroup of Tardive Dyskinesia Patients by Pharmacologic Probes

BY DANIEL C. MOORE, M.D., AND MALCOLM B. BOWERS, JR., M.D.

Some patients with tardive dyskinesia fit the cholinergic-dopaminergic imbalance theory, but some do not. In an attempt to study this heterogeneity further, the authors measured the responses of 10 patients with tardive dyskinesia to intravenous challenge doses of drugs that facilitate or inhibit acetylcholine transmission (physostigmine or benztropine, respectively). They then measured the response of these patients to an open outpatient deanol trial. They found that the responses of half of the patients followed the classic theory, 2 responded paradoxically, and 3 responded inconsistently. They suggest that there is a subgroup of tardive dyskinesia patients who fit the theory but that more research is needed to identify the subgroups who do not.

Over the past 5 years there has been increased attention to prevention and treatment of tardive dyskinesia because the frequency of this disorder seems to be increasing. In particular, the strong relationship between long-term treatment with neuroleptics and the development of the involuntary movements that characterize tardive dyskinesia has threatened therapeutic strides made in the treatment of schizophrenia and other psychotic disorders in the last 20 years.

Recent theories of tardive dyskinesia have focused on the neuropharmacologic interactions of the dopamine and acetylcholine systems in the corpus striatum of the basal ganglia. Chronic administration of neuroleptic medications is thought to cause denervation hypersensitivity of the dopamine receptors, resulting in relative dopaminergic predominance and a cholinergic-dopaminergic imbalance (1, 2). Similarly, it has been observed clinically that anticholinergic agents make tardive dyskinesia worse and that in some cases the disorder has disappeared after the anticholinergic agent has been discontinued (3–5). Klawans and Rubovits (6) showed that tardive dyskinesia could be temporarily improved with the rapid-acting anticholinesterase inhibitor physostigmine, which presumably restores the cholinergic-dopaminergic balance by increasing acetylcholine activity. Results of studies attempting to find cholinergic agents that would be effective on a long-term basis, such as deanol or choline chloride, have been mixed: some patients have improved remarkably, some have become significantly worse, and still others have responded little or not at all (7–9). These findings, plus case reports of paradoxical positive responses to the anticholinergic agent benztropine (10, 11), suggest that only a subgroup of patients with tardive dyskinesia fit the current cholinergic-dopaminergic imbalance theory.

In an attempt to study this apparent heterogeneity further, we first measured responses of patients with tardive dyskinesia to brief i.v. challenge doses of drugs that facilitate or inhibit acetylcholine transmission (physostigmine or benztropine, respectively). We then measured the subsequent response of these patients to an open outpatient deanol trial.

METHOD

Subjects

Our subjects were 10 chronic psychiatric patients, 2 men and 8 women, who were admitted to the Connecticut Mental Health Center research ward after giving informed consent. They received physical, neurologic, psychiatric, and routine laboratory examinations. Criteria for inclusion in the study included 1) visible dyskinetic movements following prolonged exposure to neuroleptics, 2) no known family history of the heredodegenerative diseases that involve dyskinetic movements, 3) no exposure to medications that may predispose to dyskinetic movements (e.g., amphetamines, L-dopa) other than neuroleptics, anticholinergics, or antidepressants, 4) duration of tardive dyskinesia of at least 6 months, and 5) no medical contraindication. All patients were kept on their routine medications, which were unchanged for at least a

month before the study. No attempt was made to tabulate the many different neuroleptic and anticholinergic medications patients had been given in the past because this information was not available in reliable form.

Drug Schedule

Once admitted, patients were allowed to become accustomed to the ward for 2 days. A videotape record was then made of their movement disorder; this served as a baseline for comparison following administration of deanol. For the next 3 days each patient spent 2 hours a day in the research room in a hospital bed with his or her head elevated. An i.v. line was placed in one arm, and a blood pressure cuff and stethoscope were attached to the other so that they could be manipulated by a nurse behind a screen. The patients could see the video camera, which was placed at the end of the bed. On the first of 3 test days the subjects received an injection of methscopolamine, .50 mg i.m., 30 minutes before the procedure began. After two 1-minute baseline videotapings 10 minutes apart, 2 ml of saline was infused over 5 minutes, followed by five 1-minute videotapings 10 minutes apart over the next hour.

The same overall procedure was followed for the next 2 days, alternating randomly between 1) methscopolamine, .50 mg i.m., 30 minutes before the procedure, and physostigmine, 2.0 mg i.v., infused over 5 minutes, and 2) saline, .5 ml i.m., 30 minutes before the procedure, and benztropine, 2.0 mg i.v., infused over 5 minutes. Patients were pretreated with methscopolamine because it blocks the unpleasant peripheral side effects of physostigmine without affecting the central actions. The effects of intravenous test doses of physostigmine or benztropine lasted less than 2 hours so that there was virtually no likelihood of drug carry-over from day 2 to day 3.

After challenge trials were completed, the patients were discharged and treated with deanol, 900 mg/day, in three divided doses. If this dose did not completely suppress the tardive dyskinesia, the dose was raised by 300 mg/day every 7 days up to a total dose of 1800 mg/day. If side effects occurred, the dose was lowered to a tolerable level and held at that level. Subjects were videotaped while receiving 900 mg, 1200 mg, 1800 mg, or the highest tolerable dose—in one case only 600 mg—for a total of 7 days.

Evaluation of Dyskinesias

Changes in dyskinetic movements were rated by choosing the most significant and disfiguring movement for each subject and counting its frequency over a 1-minute period. The correlation coefficient for interrater reliability between the two raters, one blind (M.B.B.) and one nonblind (D.C.M.), varied from .82 to .98. The average for all 10 patients was .92. Rating changes in amplitude were found to be unreliable and so were omitted.

DATA ANALYSES

We analyzed the results from the i.v. challenges and the deanol trial in a number of ways to find consistent patterns of response to the different drugs administered. We examined the data from the i.v. challenges with saline, physostigmine, and benztropine by averaging the two baseline measures and using a paired t test to compare averaged baseline scores with scores of 10, 20, 30, 40, and 50 minutes after administration of each drug. This approach produced no statistically significant results even though the observed changes seemed to show a theoretically coherent pattern in a subgroup of patients. Consequently, results in individual patients were evaluated by averaging the three scores for the 30–50-minute time period and expressing them as percent change from baseline (see table 1).

Changes with deanol were evaluated by taking the average of the four baseline scores and comparing it with the average of the four deanol scores using paired t test and percent change from baseline. Finally, patients were divided into responders and nonresponders to physostigmine and deanol to see if one could predict response to the other.

RESULTS

Challenge Drugs

The scores of 6 subjects decreased (i.e., they had fewer dyskinetic movements) with physostigmine by 14.7%–55.1% (average, 33.3%), while 4 increased their movements. Given benztropine, 7 patients increased their score by 2.3%–94.7% (average, 41.8%), while 3 had reduced movements. Since the changes occurred in both directions, the group findings did not reach significance with either drug. As can be seen in table 1, certain patients, such as patients 3, 4, 5, and 8, showed clear decreases when given physostigmine, and others (patients 6 and 7) showed dramatic increases. Still others (patients 1 through 5) showed marked increases in movements when given benztropine. Unfortunately, the striking variability of the baseline patterns made changes in either direction difficult to document statistically.

Seven patients improved when given deanol at dosages of 900–1800 mg/day. Generally, the patients given the 900–1200-mg range showed the greatest improvement. However, the improvement was not significant for the group as a whole because patients 6 and 8 had such significant increases in dyskinetic movements on deanol (225.6% and 146.7%). When these 2 patients were removed from the analysis, the deanol improvement became significant at the $p<.001$ level.

Taking the 7 patients whose movements decreased in response to deanol as a group, we examined their response to the experimental drugs by comparing each

TABLE 1
Drug Effect on Tardive Dyskinesia in 10 Patients: Percent Change from Baseline[a]

Patient Number	Saline	Physostigmine	Benztropine	Deanol	Deanol Dose (mg/day)
1	−21.9	−14.7	+49.3	−31.0	900
2	+8.0	−23.3	+43.1	−39.6	1800
3	+4.7	−37.1	+94.7	−78.3	1200
4	+6.8	−33.6	+44.5	−62.9	1200
5	−0.03	−36.2	+41.7	−100.0	1800
6	−48.2	+180.8	+2.3	+225.6	600
7	−17.8	+39.1	−5.4	0	900
				+10.5	1800
8	+25.4	−55.1	−7.8	+146.7	1800
9	+15.4	+21.4	+17.1	−33.7	900
10	−64.7	+11.8	−5.4	−24.7	900

[a]A positive percent change indicates an increase in the number of dyskinetic movements observed.

time period with the baseline to see if there was a significant trend. With benztropine, the dyskinetic movements of these patients were significantly increased ($p<.05$) at 20, 40, and 50 minutes after drug administration. There were no statistically significant changes with physostigmine or saline.

The pattern of the responses of patients 1 through 5 fits the current cholinergic-dopaminergic imbalance theory (see table 1): cholinergic agonists like physostigmine and deanol improved tardive dyskinesia and cholinergic antagonists like benztropine made it worse. Patients 6 and 7 showed a paradoxical pattern, with increased movements in response to physostigmine and deanol and no change in response to benztropine. The final 3 patients did not fit any consistent theoretical pattern.

DISCUSSION

Until recently tardive dyskinesia has been viewed as a single disease with a single etiology. Our findings show that 50% of the patients with tardive dyskinesia whom we tested followed the classic cholinergic-dopaminergic imbalance theory. They formed a major subgroup within the larger group of tardive dyskinesia patients and could be distinguished by pharmacologic challenges with cholinergic and anticholinergic agents. Casey and Denney (12) had similar results in an elegant study of 6 patients. They challenged each patient with L-dopa (a dopamine agonist), droperidol (a dopamine antagonist), physostigmine, and benztropine. They then placed patients on a double-blind deanol and placebo trial and found that 3 patients improved significantly on physostigmine, droperidol, and deanol in accordance with current theory, while 3 other patients became significantly worse on the same three drugs and better on benztropine. In other words, approximately 50% of their patients fit the current pharmacologic theory that dopamine antagonists and cholinergic agonists will decrease tardive dyskinesia, a finding that agrees with our own results, i.e., 5 out of 10 patients improved on physostigmine and deanol and became worse on benztropine.

A survey of the literature on the use of cholinergic agents in tardive dyskinesia reveals a consistent recurrence of this 50% figure, which may represent a subgroup. For instance, eight different investigators, who have administered physostigmine in doses of 1–3 mg i.v. to a total of 53 tardive dyskinesia patients, found that 28 (52.8%) showed decreased movements, 10 (18.9%) showed increased movements, and 15 (28.3%) showed no change (6, 8, 12–17). Similar figures emerge from i.v. trials of benztropine, 2.0 mg, or scopolamine, 1 mg. Of 24 cases studied by four investigators, 12 (50%) followed the theoretical pattern by getting worse, while 5 (20.8%) had decreased symptoms and 7 (29.2%) showed no change (6, 11, 12, 17).

Casey (18) reviewed the therapeutic use of deanol in tardive dyskinesia. Using the rigorous criteria for improvement of 50% change in symptoms, he noted that of 75 cases reported in the literature, 30 patients improved (40%), 44 had a slight or no response (58.7%), and 1 became worse (1.3%). Looking at double-blind studies only, he found that of 29 patients, only 7 (24.1%) significantly improved. He noted no patient characteristics or clinical aspects of tardive dyskinesia that would predict response to deanol.

By way of comparison, a double-blind crossover study with choline chloride, a more likely precursor of acetylcholine (19), found that 5 of 20 patients improved greatly and 4 patients improved moderately. Movements were unchanged in 10 patients and worse in 1. This 45% improvement rate is the best reported to date with longer-acting cholinergic agents.

All four drugs seem to show a consistent subgroup of approximately 40%–50% of patients who respond according to current pharmacologic theory. However, at this stage of research in tardive dyskinesia, we cannot rule out a number of possible sources of experimental variability that might explain the lack of uniformity of response on a technical basis. Many authors have discussed, and Simpson and associates (20) have documented, the day-to-day changes in tardive dyski-

nesia. Combined with the tendency of patients either to suppress or release movements when anxious or observed, this variability makes changes in movements extremely hard to score reliably in both acute and chronic drug trials. Another source of confusion is the failure of most investigators to control for a number of factors that are generally acknowledged as influencing the severity of tardive dyskinesia. These include maintaining patients on anticholinergics during drug trials (6, 9, 12–14), discontinuing psychotropic medication immediately before administering experimental drugs (8, 17, 20, 21), or disregarding the duration of tardive dyskinesia (7, 8, 11, 20).

Further studies will be necessary to control for these sources of variability more rigorously, and the result of this more careful attention to experimental method may be the development of subgroups of patients with tardive dyskinesia who respond more uniformly to specific drugs. These subgroups might be based on age, sex, duration of tardive dyskinesia, total duration of neuroleptic treatment, diagnosis, or some other as yet unknown factor. We have recently shown that a group of patients with tardive dyskinesia was heterogeneous with respect to CSF measures of central dopamine activity (22). Our present study suggests that approximately 50% of tardive dyskinesia patients can be identified as responders to cholinergic treatment consistent with the cholinergic-dopaminergic imbalance theory. Just as intriguing is the etiology of tardive dyskinesia in the 50% who do not respond in the expected fashion to cholinergic agents. Advanced age and diagnosis of organic brain syndrome are important risk factors for senile (spontaneous) dyskinesia as well as for tardive dyskinesia, and it may be that older or demented patients have a more permanent lesion that is less responsive to pharmacologic intervention. Still another subgroup of patients seems to react paradoxically, such as our patients 6 and 7, who had increased movements when given physostigmine and deanol. Their response is similar to that of 3 out of 6 of Casey and Denney's patients, who became worse on physostigmine, droperidol, and deanol (12). They may have changes in different areas of the corpus striatum, resulting in a "hypercholinergic" form responsive to anticholinergics as theorized by Casey and Denney (12) and Gerlach and associates (23).

Studies that treat all tardive dyskinesias as a uniform clinical entity for statistical purposes may obscure significant clinical responses of subgroups of patients who, as shown above, may respond in diametrically opposite ways to the same drug. To understand and treat tardive dyskinesia more successfully we will need to try multiple drugs on the same population of patients and then examine individual responses to identify specific subtypes.

The Psychiatry Internship and the Development of Professional Identity

BY MARGARET M. GILMORE, M.D., AND SAMUEL W. PERRY III, M.D.

Advocates of the psychiatry internship believe the experience fosters professional maturity. The authors examined the maturing process of 10 psychiatry residents during their internship year. Changes in the interns' professional identity including expectations of self and others are described and seen as a goal of the experience. The authors outline danger signals of poor professional development and suggest interventions to help interns resolve conflicts.

The purpose of an internship for psychiatrists has been debated for years. In 1970 the American Board of Psychiatry and Neurology eliminated the internship requirement; in 1975 the Board reinstituted it in modified form. Controversy ensued as educators struggled to find—and to fund—a meaningful experience (1-3). Many arguments did not distinguish between what the internship offered in the acquisition of medical skills and what it offered in helping the young physician to mature professionally. The acquisition of medical knowledge does not justify the internship year. Medical facts alone can be taught more concisely, and certainly more comfortably, to a psychiatry resident than to an exhausted intern. The requirement may be justified if the internship catalyzes a maturational process that is essential to becoming a psychiatrist. In this paper we examine how the internship fosters that process.

Many observers have suggested that the internship promotes professional maturity, but this notion has not been documented (4). Sociological studies have described the broad attitudinal changes that accrue in different hospital environments and historical periods (5, 6). These reports have not been supplemented by an examination of the psychological changes. Karasu and associates (7) compared psychiatry residents who had completed an internship with those who had not and found that the internship residents were considered more proficient in relating to staff and patients, more capable in their handling of medical problems, and more responsive in emergencies. In a follow-up study (8) Karasu and Stein found that internship residents were rated by supervisors as having better clinical judgment and that these residents carried larger caseloads, had fewer patients drop out of treatment, and prescribed medication more often. They concluded that "the internship does have a maturing influence." Unfortunately, the studies did not define professional maturity. In addition, because these studies were retrospective and uncontrolled, they could not determine whether the internship residents were more mature to begin with—and perhaps chose to take an internship for that reason.

THE STUDY GROUP

We decided to conduct a prospective study to examine what constitutes professional maturity and how the internship year helps it develop. Throughout one year, we observed the professional development of 10 psychiatric residents during their internship year at New York Hospital. Each resident spent approximately 6 months on general medical services, including 2 months in private medicine, 1-2 months on a specialized cancer treatment service, 1 month on neurology, 1 month on pediatrics, and 5 months on psychiatric services, including 2 months in a walk-in clinic and 1 month each on three inpatient units specializing in the treatment of geriatric, alcoholic, and research patients. Our observations took place in a discussion group that we established in order to provide a "home base" for the interns who were rotating singly from service to service.

Once a week the 12 of us gathered to review case vignettes, reactions to patients, interactions with staff, ideas, and feelings—whatever seemed related to the experience of being an intern and becoming a physician. Initially, attendance at the group was excellent, but it tapered in the last two months. We stated from the start that the group would not focus on individual personality styles or intimate problems. The primary objective of the group would be to examine the psychological issues relevant to the internship experience.

Only after several weeks did we appreciate a second objective of the group: the process of examining the conflicts of internship was helpful in resolving them.

GROUP DATA

The group study gradually revealed the psychological conflicts that the internship evokes. We learned that the training experience presents opposing views of one's professional self-worth. The interns expressed conflicts between feeling knowledgeable or ignorant, certain or uncertain, helpful or helpless, authoritative or deferential, and responsible or subordinate.

These conflicts were particularly acute for the residents during their medical and pediatric rotations, where they were required to make rapid diagnostic decisions, work endless hours and perform invasive procedures such as venipunctures, lumbar punctures, and liver biopsies, and institute complicated, unproven, and sometimes life-threatening treatment protocols for cancer patients. They could not avoid an emotional involvement with frightened patients and their disrupted families. As the residents recounted case vignettes they recognized the complex contributions of family involvement, medical knowledge, and socioeconomic variables that contribute to decisions to initiate or terminate intensive medical treatment. While in pediatrics, the residents were forced to confront their own painful emotions about youthful patients and to recognize the effect these feelings had on their treatment decisions. Simultaneously, the interns were expected to be receptive, inexperienced students, to follow the advice of their attending physicians, and to follow residents' directions about chart notes, daily routines, filling out forms, and getting X rays.

The conflict between feeling omnipotent and impotent is not exclusive to this year of training, but the candid group discussions repeatedly emphasized how the internship uniquely polarizes these extremes. The unshakable presence of physical illness forced the interns actively to confront this conflict. The interns—unlike psychiatry residents—could not retreat into a position of passive neutrality. The option of psychiatrists to defer responsibility and deflect the problem back onto the patient in the privacy of an office is not available to the intern on a medical, surgical, or pediatric service. During a patient's cardiac arrest, not to decide is to decide! The experience thereby not only intensified conflicts between omnipotence and impotence, but through its requirement for action pressed for an adaptive resolution.

The early group discussions exposed only one pole of this conflict: the impotence. The interns complained of feeling overwhelmed, inexperienced, and inadequate. They felt like "imposters" when writing orders or doing procedures. One intern thought the nurses must be joking when they addressed her as "doctor"—after all, the nurses knew far more than she did, and they certainly knew she was not *really* a doctor. Conversations centered on the most ill patients. The interns, an insightful group, realized that because they felt vulnerable and helpless themselves, they sympathetically identified with the most dependent patients. The interns were less quick to realize that—also like these neediest patients—they had developed unrealistic expectations of their own "caretakers" by overidealizing attending physicians and by viewing residents as incredibly knowledgeable. Having a sharp resident provided a sense of security—and a sense of panic when that maven left for the day and the interns were confronted with handling patients on their own.

This idealization of the attending staff and residents had a short life. Although the interns, in response to their own feelings of inadequacy and frustration, continued to believe that they were merely "puppets on a string," they stopped regarding their superiors as so grand. The interns began to express contempt for residents, attending physicians, and hospital administrators who had "let them down" by not fulfilling the great expectations of a top training program. Elder physicians were "incompetent and outdated," younger attending physicians were "ambitious and insensitive," and residents were "competitive and unavailable." A litany of complaints permeated the group; the interns sharply criticized a cancer research protocol, picked apart a treatment plan by a prestigious attending physician, and derided a resident for failing to order further tests for a dying patient. This disappointment reached a crescendo in the group when a patient committed suicide in the psychiatric hospital. The interns greeted the news with angry incredulity. How could it happen? Why couldn't the staff stop him? Why didn't the psychiatrist predict the suicide and take proper precautions?

During this phase the interns regarded their superiors not only as incompetent but malevolent as well. They felt they were handmaidens designated to do the undesirable work so that private practice physicians could live comfortably. One group member suggested that the internship is the result of a necessary financial collusion between hospital administrators and exploitive attending physicians. Other members believed the only rationale for the experience was that it was a type of hazing ritual for the rite of passage into the medical guild. They talked about the need of insecure, older physicians to inflate themselves by speaking about "days of the giants, when ships were made of wood and men were made of steel."

The interns' failure to find any value in the internship experience reached its highest pitch when one of the group members decided to take a leave of absence. The interns' rotation schedules had to be revised. They were irate. They felt maligned, "political

pawns" whose lives were being manipulated for the sake of the department. The prearranged schedule was the one thing they had relied on. Now that, too, was being taken away.

Their general disappointment in their residents and attending physicians and their specific disappointment in having to readjust their schedules catalyzed a dramatic change in the interns' view of themselves. Feelings of being helpless victims and incompetent neophytes were replaced with feelings of being powerful, prestigious, and influential. "We really keep the hospital going." "We're the ones on the inside track." "The attendings come and go but we're where it's at—on top of things." Esoteric medical jargon then infiltrated the group discussions as a symbol of the interns' acquired status. An intern mentioned that she had walked out of the psychiatry conference on her medical service because "all they do is talk," and she felt that was a meaningless exercise when one was treating people who were "really sick." Another intern boasted that he had made the important management decisions regarding a patient while the rest of the staff vacillated. Despite the complexity of the issues involved, the intern refuted any possibility that his judgment might not be absolutely right. The implication was that if the interns could not rely on attending physicians and residents for foolproof answers, at least they could rely on themselves. They bragged to each other about their fast workups and diagnostic acumen. Their complaints of overwork decreased. One intern even complained of having an insufficient work load!

At approximately midpoint in the year the group gradually entered its third phase. Whereas during the first phase the interns saw themselves as incompetent, with power delegated to others, and whereas in the second phase the interns devalued their superiors and assumed the power themselves, the third phase was characterized by their realization that neither they nor others were omnipotent. As one intern stated succinctly, "Medicine isn't magic—not the pills, not the people."

With this realization came a heaviness in the group. The interns' despair over recognizing limitations made difficult problems seem utterly hopeless. "What can doctors really do? Patients never really get well. They just die or stay sick a long time." Group members compared notes about patients whom one intern had admitted, treated, and discharged, only to have another intern readmit the patient for the same medical problems a few weeks later. The despair over therapeutics was compounded by the interns' disappointment about what gratification they could expect from their work. Patients would not worship the doctor who did not cure them, and they might even resent the doctor who inflicted pain. One intern poignantly described her conflict over drawing blood from an adolescent who accused her of torturing him. When their discouragement became most intense, the interns discussed the "worthless" and "meaningless" nature of the internship in particular and of medicine in general. One intern considered quitting, and others discussed returning home "tearful." The group agreed the year was not necessary for those planning careers in psychiatry.

During the last three months the group discussions shifted into a fourth and final phase. The interns' mood improved, and they began to express pride in what they had accomplished—or at least survived. Although still disappointed in the limitations of medicine and of physicians, the interns expressed a more realistic appraisal. They regarded physicians as human beings who get tired, make mistakes, but take reasonably good care of patients. The interns' descriptions of patients gained new dimensions as well; they regarded them as both helpless and helpful, cooperative and uncooperative. Maintaining an all-lovable, infallible image with patients became less of a goal. Members reported vignettes about setting limits with patients even when doing so caused resentment, such as refusing to sign a patient's disability form. The interns were more comfortable in experiencing anger with patients who tried to frustrate or humiliate them or make excessive demands, and they distinguished this anger from the unreasonable anger at patients who did not respond to treatment.

USE OF GROUP PROCESS

The discussion group provided both a way of determining whether an intern was inflexibly stuck in one of the phases we have described (feeling helpless, omnipotent, depressed, or cynical) and an environment to help the interns find more adaptive solutions. Through trial and error, we found that several technical maneuvers were useful in that process.

During the first phase, when the interns revealed an exaggerated sense of their own inadequacy, our tactic was to refuse to accept these notions. We asked the interns what was being accomplished by their feeling so helpless. This question forced the interns to recognize that their sense of incompetency was a distortion. Furthermore, as the interns used their insight and intellect to analyze the question, the process of using these more mature ego functions short-circuited the regressive wish to be taken care of.

Another maneuver during this first phase was to reject the interns' helplessness within the discussion group. The interns expected us to structure the group, relieve the silences, and come up with the final answers. We refused this overidealized role. Instead, we allowed silences and discussed our own mistakes and doubts about patient care. Similarly, during the crisis when one intern took a leave of absence, we refused to accept their notion that we should be able to prevent or correct such situations. We pointed out that such

things are unavoidable. As the interns assumed more responsibility for making the best of this bad situation, they recognized that they had previously viewed themselves in the subordinate position of being interns in order to feel entitled to be taken care of. By the end of this first phase the interns understood that making oneself dependent does not ensure that an all-providing, dependable parent will appear.

During the second phase the group process challenged the interns' fragile grandiosity while at the same time offering collegial support. We helped the interns see that their need to feel admired—to be the giants who rescued mankind from the grip of disease—was an attempt to master feelings of uncertainty, futility, and aloneness. When a member of the group described how brilliantly he or she had handled a case or managed an inhuman work load, the other members would respectfully permit the intern to boast, but in time they would gently question the idealized account. The mutual support of the group members and the sharing of uncertainties became a more adaptive way of facing their limitations as physicians.

The devaluation of attending physicians in the second phase posed a special challenge to the group coleaders. There was a great temptation for us to identify with the attending physicians who were being berated and to counterattack defensively. We tried to resist this temptation. We reminded ourselves that to counterattack would only increase the interns' insecurity and thus increase their need to feel omnipotent. However, we did not want to appear helpless. We found that an effective way to interact with the interns was to agree to disagree by stating our opinions firmly so that the interns knew what we did and did not believe. We also tried to depersonalize the discussions and get the residents to face their own conflicts rather than attack authority. We asked more general questions. Where can a physician reasonably expect to get gratification? From work? From the admiration of patients? From monetary reward? From the improvement of patients? From a final job well done?

The group appeared to have its greatest value during the third phase, when it definitely helped the interns cope with their grief over lost self-idealizations. By this time we had sufficient data to interpret the interns' despair. We pointed out that the demands and limitations of the internship were forcing the group members to come to terms with who they were and who they were not. Although these interpretations were useful, the group process was even more helpful. It provided a supportive place where the interns could withdraw for a moment to contemplate the impact of the internship experience. During this phase we also had to confront our own limitations and resist the temptation to try "to make it come out all right" for the interns. They needed to understand that physicians cannot cure the unavoidable disappointments, losses, and frustrations of life.

During the final phase, as the interns established more realistic professional expectations for themselves and for others, the group reinforced this process by inviting senior faculty members to attend the group and discuss conflicts of their own professional lives. The chairman, vice-chairman, director of training, and the coordinator for the next year all came and informally revealed their professional goals, frustrations, successes, and failures.

DISCUSSION AND CONCLUSIONS

The group data supported the view of internship as a crisis in professional identity. The pattern in which all of the interns passed through similar phases as they attempted to cope with the stress of developing a more consolidated professional identity conforms to the theory of phase resolution of crisis (9, 10). Psychosocial and psychological studies (11–15) have emphasized that establishing a realistic appraisal of oneself is not just the struggle of the young child, but a lifelong process with definable critical periods and developmental tasks. Internship can be seen as just such a critical period—a physician's "professional adolescence" when issues about professional self-worth are heightened. Interns are forced to close the gap between their own ideal self-expectations and exaggerated sense of inadequacy.

The study group revealed the four phases of conflict resolution and some techniques for fostering intern growth: 1) a phase of helplessness when the interns overidentify with the patients and view themselves as totally incompetent and delegate exaggerated powers to others; 2) a phase of aggrandizement when the interns inflate themselves with magical expectations for cure and admiration; 3) a phase of despair when the interns grieve over the lost omnipotence in themselves and others; and 4) a phase of transformation when the interns set more reasonable expectations for themselves and others, accept their limitations, and continue to grow by finding positive aspects in their work and colleagues with which to identify.

Our study group also helped us to recognize when interns are in trouble with their professional maturity. If interns remain stuck in phase 1, they will be paralyzed by uncertainty, will be unwilling to assume responsibility in difficult situations, and will rely too heavily on colleagues, consultants, or the institution of medicine rather than assuming an autonomous position. Similarly, if interns remain stuck in phase 2, they will avoid the complex, chronically ill, or dying patients who challenge their magical view of themselves. They will also resent patients who do not love and admire them and will be demeaning and contemptuous toward colleagues who are less than perfect. Interns' clinical judgment will be impaired by their wish to please patients at all costs, which will lead them to avoid per-

forming painful procedures or to prescribe unnecessary medications. Finally, if interns remain stuck in phase 3, they will be forever disenchanted with medicine and with themselves, constantly frustrated about how little they and the profession have to offer.

The group study was a first step in defining professional maturity. Mature physicians can simultaneously accept their limitations and maintain their therapeutic optimism and concern for patients. Their clinical judgment will be impaired by neither a need to be omnipotent nor a therapeutic nihilism. Mature physicians will be able to tolerate their emotional involvement with chronically ill and dying patients without seeing them as totally helpless victims or biological specimens. They will recognize the complexities of family ties, socioeconomic variables, and medical knowledge, which operate in determining patient care.

We recognize that this study supplies neither a complete definition of professional maturity nor a definitive answer about the questionable value of medical rotations for the psychiatric resident. However, it is a beginning.

Race Bias in the Diagnosis and Disposition of Violent Adolescents

BY DOROTHY OTNOW LEWIS, M.D., SHELLEY S. SHANOK, M.P.H., ROBERT J. COHEN, ED.D., MICHAEL KLIGFELD, M.D., AND GIOVANNI FRISONE, PH.D.

The authors compared psychiatric symptoms, violent behaviors, and medical histories of an entire one-year sample of adolescents from the same community who were sent either to the correctional school or the only state hospital adolescent psychiatric unit serving the area. The initial hypothesis that the incarcerated group would be equally disturbed but more violent than the hospitalized group was contradicted. Violence as well as severe psychiatric symptomatology was equally prominent in the two groups. The most powerful variables distinguishing the groups were race, accidents, and injuries (especially head injury), and sex. The medical and social implications of the findings are discussed.

In this paper we report clinical and epidemiological evidence of race bias in the ultimate disposition of aggressive adolescents. We shall report similarities and differences between adolescents from the same community sent either to a correctional institution or to a psychiatric hospital during a single year in the mid 1970s.

In our previous work (1–5) we have reported the existence of severe psychopathology in a delinquent population. We have also reported that incarcerated delinquents have extremely adverse medical histories (6–8) and are characterized by many neuropsychiatric signs and symptoms (9). Having found such a high prevalence of psychotic symptoms, neurological impairment, and serious medical problems in incarcerated youngsters, we wondered what factors might influence a psychiatrically disturbed adolescent's being sent to a correctional facility rather than a treatment facility. We hypothesized that the behavior of incarcerated adolescents would be characterized primarily by aggression toward others, whereas the behavior of psychiatrically hospitalized adolescents would be more withdrawn, self-destructive, or, if violent, would be expressed within the home. We also wondered whether such factors as race and sex affected where a child was sent.

METHOD

Samples

Our two samples consisted of 1) all adolescents from an urban area of Connecticut who in a given year were sent to the only correctional school in the state and 2) all adolescents from the same area who in that same year were admitted to the adolescent unit of the only state psychiatric hospital serving the same area. Since both populations came predominantly from the lowest socioeconomic sectors of the area, private hospitalization was seldom available. The few residential treatment facilities for the area had waiting lists and tended to accept younger children. Except for a general-hospital-based crisis unit, there were no other readily available alternative placements for this population.

The sample of adolescents sent to a correctional school consisted of 63 youngsters, and the sample sent to an adolescent unit consisted of 35. Six children had been to both institutions and were included in the correctional school sample because this was their ultimate placement.

Because of differing acceptance criteria regarding age, the average age of the correctional school sample at the time of our study was 15.56 years and that of the adolescent unit children was 17.01 years, a significant difference ($t=6.151$, $p<.001$). To correct for possible bias due to age differences between the two groups, all data regarding medical histories were analyzed for two time periods, before age 4 years and through age 16 years.

Settings

The two institutions were situated in the same town, approximately 25 miles from the urban area being studied and only minutes from each other by car. Thus they were theoretically equally accessible to the youngsters. Both institutions had open and closed fa-

cilities and were equipped to care for aggressive children. The adolescent service had 16 beds reserved for boys and 12 for girls. The correctional school had 4 cottages of 30 beds each for boys and 2 cottages of 30 beds each for girls.

Sources of Data

Data were gathered from the records of the adolescent unit of the state hospital, the records of the correctional school, all available previous psychiatric evaluations, and the records of the largest general hospital serving the urban area. This hospital had been used by 83.9% of the correctional school sample and 88.2% of the adolescent unit sample. The advantages and disadvantages of using these hospital records to gather medical information have been discussed in another report (7).

The following factors were explored: 1) violent and nonviolent behaviors influencing institutionalization, 2) quality of psychiatric symptoms mentioned, 3) number of general hospital visits, 4) use of particular services, such as the emergency room, clinics, and wards, 5) the nature of medical problems (e.g., perinatal difficulties, accidents and injuries, head and face injuries, and respiratory infections), 6) age, 7) sex, and 8) race. Although socioeconomic class could not always be established from the records, the great majority of adolescents in both groups came from the lowest socioeconomic sectors of the urban population.

For purposes of assessing the presence or absence of violent behaviors, violence was defined as any mention in the records of arson and/or serious physical violence directed against other people. That is, murder, serious assault in which injury to another person occurred, sexual assault, and threatening with a weapon were classified as violent.

FINDINGS

Behaviors

Our assumption that the psychiatrically hospitalized adolescents would be demonstrably less violent than their incarcerated peers was refuted by the data available. Of the 33 hospitalized adolescents about whom information regarding behaviors was available, 25 (76%) had extremely violent acts documented in their charts. In fact, according to their clinical charts, 19 of these hospitalized adolescents were known to the police or to the courts for a variety of more or less violent antisocial acts; however, for reasons that were not explicit, the courts had not sent them to the correctional institution.

The extreme violence manifested by the psychiatrically hospitalized youngsters is evident in the following examples:

One boy had been arrested for sexual assault, vandalism, indecent exposure, and beating an aged relative. Another had committed armed robbery, had sold drugs, and had a great number of minor charges against him. One boy had knifed another boy and had stated, "I get real violent. I don't stop until I see they're bleeding." One boy had threatened his mother's life, was arrested, released on $2,500 bail, and then sent to the hospital after injuring a policeman. Another boy, charged with burglary, fire-setting, larceny, and reckless endangerment, had allegedly homosexually attacked a small child and had taken his father's gun and tried to kill the father. Another boy had attempted to choke a younger sibling and had subsequently been ejected from a Salvation Army shelter when he assaulted another patron; a gun had been confiscated from him at one hospital, and bullets had been confiscated from him at another.

Physical aggression was characteristic of hospitalized girls as well as hospitalized boys, although it seemed to be somewhat less violent in nature. One girl had been expelled from a residential school because of violent behaviors and had subsequently assaulted a hospital staff member. Another had had a history of assaultiveness since second grade, had punched another patient in the mouth, and had threatened to harm staff. Another girl, who had also been expelled from school because of assaultiveness, had slapped around a child for whom she was babysitting and had physically assaulted the child's mother.

Of the 8 hospitalized adolescents not classified as violent about whom behavioral information existed, 5 had histories either of violence toward property (e.g., smashing furniture or breach of the peace) and/or threatening others with violence. Counter to our prediction, only 3 of the hospitalized adolescents were characterized primarily by self-destructive behaviors. Moreover, violent behaviors clearly were not limited to violence within the home.

Although it is not possible to compare exactly the prevalence and degree of violence in the two samples because the assessments of violence are inexact, a review of correctional school records indicated that 46 (73%) of the incarcerated sample had committed violent acts similar in nature to the acts of the 25 most violent hospitalized adolescents (e.g., assault, armed robbery, and sexual assault). Thus as far as we could determine, violence seemed to be as characteristic of the hospitalized sample as it was of the incarcerated sample. In fact, the majority of hospitalized youngsters had been arrested but not incarcerated for violent acts.

Psychopathology

Psychiatric hospital and correctional school records were maintained for clinical purposes and not for research; therefore, the clinical data were not uniform. All of the hospitalized children had been seen by a psychiatrist; some had also been seen by a psychologist. Almost all of the incarcerated children had received a

[b]Data on perinatal problems existed for 15 hospitalized and 31 incarcerated adolescents. Data in the other categories are based on 34 hospitalized and 59 incarcerated adolescents.

psychological evaluation, and many had had psychiatric evaluations as well. Both groups had received social work assessments. The majority of children in both groups had received previous psychiatric or psychological assessments in schools, clinics, or other residential settings, and these were also reviewed.

Of the 33 psychiatrically hospitalized adolescents for whom adequate clinical data existed, 13 were described as showing psychotic symptoms and 10 were described as having borderline or equivocal manifestations of psychotic disorders. Of the 60 incarcerated children for whom adequate clinical data existed, 14 were described as demonstrating psychotic symptoms and 17 as showing equivocal evidence of psychotic symptoms.

Because of the variability in the quality of clinical data available, we felt that it made little sense to make statistical comparisons between the prevalence of psychosis or borderline psychosis in the two groups. Suffice it to say that psychotic symptoms were reported to be prevalent in both groups.

Medical Histories

As can be seen in tables 1 and 2 hospitalized and incarcerated adolescents made similar numbers of hospital contacts and were equally likely to have sustained perinatal difficulties. Incarcerated adolescents, however, had significantly more accidents and injuries, specifically head or face injuries. It is noteworthy that the incarcerated children were as likely as the psychiatrically hospitalized children to have had psychiatric problems noted at the general hospital and to have been referred for psychiatric or social work evaluations.

Comparison of Medical Histories of Adolescents from Each Sample Born at the General Hospital

Although the correctional school youngsters had more adverse medical histories through age 16 years than did the adolescent unit youngsters, it was possible that differences in numbers of visits and numbers of injuries reflected length of residence in the area rather than actual numbers of medical events. More correctional school youngsters (N=28) than adolescent unit youngsters (N=9) had been born at the general hospital. Although this difference was not significant, it could conceivably have skewed our findings. We therefore decided to compare the medical histories of adolescents in each sample who had been born at the general hospital in question.

Tables 3 and 4 show the similarities and differences between the medical histories of children in each sample born at the general hospital studied.

Again, the two groups had similar numbers of visits and a similarly high prevalence of perinatal difficulties. However, once more, accidents and injuries, specifically head or face trauma, significantly distinguished the groups: incarcerated children had the greater number of injuries. Of note is the finding that the incarcerated group made significantly more hospital visits and had somewhat more accidents and injuries before age 4 years.

Sex and Race of Entire Samples

As can be seen in table 5 girls were more likely to be hospitalized and boys were more likely to be incarcerated. Furthermore, a significantly greater proportion of black youngsters were sent to the correctional institution than were hospitalized. When the data were analyzed for sex and race, the ratio of black to white girls did not differ significantly within the two institutions. On the other hand, the ratio of black to white boys was significantly greater in the correctional school than in the adolescent unit of the hospital.

TABLE 4
Number and Percent of Psychiatrically Hospitalized and Incarcerated Adolescents Born at the General Hospital with Particular Medical Problems Through Age 16[a]

	Hospitalized Adolescents[b]		Incarcerated Adolescents[b]	
Medical Problem	N	%	N	%
Perinatal problems	6	75.0	17	60.7
Child abuse	3	33.3	10	35.7
Psychiatric symptoms	5	55.6	15	53.6
Psychiatric/social work consultation	3	33.3	11	39.3

[a]All of the comparisons were nonsignificant according to Fisher's exact test.
[b]Percents are based on the actual number of subjects on whom information was available for each category. Data on perinatal problems existed for 8 psychiatrically hospitalized adolescents. All other data on psychiatrically hospitalized adolescents were based on 9 subjects. Data in all categories for incarcerated adolescents were based on 28 subjects.

Multiple Regression Analyses

Having found the quality and prevalence of violence to be similar in the two groups, we wondered which of the medical or demographic variables that we were able to investigate distinguished the correctional school sample from the adolescent unit sample most clearly. We therefore conducted a multiple regression analysis, using group membership as the dependent variable (i.e., correctional school sample born at the hospital versus adolescent unit sample born at the hospital) and the following independent variables: 1) perinatal problems, 2) number of emergency room visits through age 16, 3) number of ward admissions through age 16, 4) number of accidents and injuries through age 16, 5) number of head and face injuries through age 16, 6) number of respiratory infections through age 16, 7) sex, and 8) race.

The most powerful variable distinguishing the groups was race, which accounted for 18.1% of the variance. Numbers of accidents and injuries through age 16 years accounted for 11% of the variance; the correctional school sample had the greater number. Sex accounted for 6.8% of the variance. Perinatal difficulties accounted for 4% of the variance: the hospitalized sample had more perinatal problems. The above factors together accounted for 39.9% of the entire variance (R=.632).

When we repeated the multiple regression analysis using the variables of accidents and injuries and head and face injuries as discontinuous variables (i.e., accident or injury through age 16, yes or no, and head or face injury through age 16, yes or no), the picture changed. The most powerful factor distinguishing the two groups was the fact of having received a head or face injury before age 17 years. This factor accounted for 30.2% of the variance: a greater proportion of correctional school adolescents had at one time or another sustained a head or face injury requiring hospital care. Race accounted for 16.7% of the variance. Perinatal difficulties accounted for 6.1% of the variance: the adolescent unit group had a greater prevalence of perinatal problems. Sex was the fourth most powerful predictor, accounting for 4.8% of the variance. These four factors accounted for 57.8% of the variance (R=.760).

Factors Distinguishing Incarcerated from Hospitalized Adolescents Before Age 4

We wondered whether a constellation of medical and/or demographic factors existed that distinguished the two groups early in life. We therefore conducted the same kinds of multiple regression analyses using age 4 as the cutoff point. Our dependent variable, again, was group membership (i.e., correctional school sample born at the hospital versus adolescent unit sample born at the hospital), and our independent variables were 1) perinatal problems, 2) number of emergency room visits before age 4 years, 3) number of ward admissions before age 4 years, 4) number of accidents and injuries before age 4 years, 5) number of head and face injuries before age 4 years, 6) number of respiratory illnesses before age 4 years, 7) sex, and 8) race.

We found that, again, race was the most powerful predictor of group membership, accounting for 18.1% of the variance. Sex predicted 8.3% of the variance, and number of emergency room visits accounted for 6.4% of the variance: correctional school children had

TABLE 5
Sex and Race of 35 Psychiatrically Hospitalized and 63 Incarcerated Adolescents

Item	Hospitalized Adolescents N	Hospitalized Adolescents %	Incarcerated Adolescents N	Incarcerated Adolescents %	χ^2	Significance

White and female	7	53.8	4	36.4		
Comparison					.198	n.s.

more emergency room visits. These three factors accounted for 33.3% of the total variance (R=.577).

When accidents and injuries before age 4 years and head and face injuries before age 4 years were treated as discontinuous variables (i.e., accident or injury before 4 years, yes or no, and head or face injury before 4 years, yes or no), the following findings emerged: race accounted for 18.1% of the variance, sex for 8.8%, and having had a hospital-treated accident or injury before age 4 years an additional 7.2%. Incarcerated adolescents were more likely to have been treated at the hospital for an injury or accident before age 4. These three factors together accounted for 34.1% of the total variance (R=.584). Thus the two groups could be distinguished from each other before their fourth birthdays.

DISCUSSION

Counter to our initial hypothesis, the results of this study suggest that the majority of adolescents hospitalized in the state psychiatric facility were as violent as their incarcerated peers. Whether or not the two samples had equally severe psychiatric symptomatology was difficult to ascertain, but our clinical and epidemiological findings suggest that both samples were essentially psychiatrically similar. Clinical descriptions suggested that a few of the hospitalized youngsters were more flamboyantly and therefore obviously psychotic than the incarcerated group. Consonant with psychiatric findings was the fact that both groups had similarly poor medical histories. Paradoxically, incarcerated adolescents were significantly more likely to have sustained head injury requiring hospital care. It is ironic that head injury, a medical event that one might assume would correlate with subsequent psychiatric treatment, was strongly associated with subsequent incarceration.

Our findings regarding the disposition of violently aggressive adolescent girls represents one of the few examples in our society of the operation of what would seem to be a reverse sex bias. Aggressive behaviors that in adolescent boys are often treated as the deliberate acts of healthy youngsters are more likely to be recognized as psychologically aberrant when performed by girls.

A most striking factor distinguishing the two groups was neither behavior nor psychopathology. It was race. In the lower socioeconomic sectors of the urban area studied, violent, disturbed black adolescents were incarcerated; violent, disturbed white adolescents were hospitalized.

There are several plausible explanations for the fact that aggressive, psychiatrically disturbed black adolescents are less likely than similarly disturbed and aggressive white adolescents to receive psychiatric treatment. The history of psychiatry in the United States bespeaks a tendency for white psychiatrists to overlook or rationalize as normal the signs and symptoms of psychopathology in black individuals (10–12). The exclusion of black patients from white psychiatric facilities was justified in the past by the presumption that black people were essentially different from white people—that they were cheerful and not prone to psychiatric illness and therefore were to be assessed by means of different standards of mental health (13).

These early-twentieth-century rationalizations have persisted. For example, Fischer (14) stated, "What is called sick or deviant behavior for one group may actually be adaptive—or functional—in another." Similarly, White (15) asserted, "What the dominant culture deems deviant or antisocial behavior might indeed be the functioning of a healthy black psyche."

To this day psychiatric professionals are taught to guard against the possibility of diagnosing pathological deviance in a different racial population. It is our experience that such advice and training have often led white professionals to dismiss the signs of psychotic and/or organic disorders in black patients as culturally appropriate. Hallucinations have been dismissed as

excessive religiosity, paranoid ideation and behaviors as healthy adaptation to hostile surroundings, and learning disabilities based on CNS dysfunction as evidence of cultural deprivation. As Comer (16) said so well, "Well-meaning social scientists . . . attempting to explain the circumstances in the black community, have sometimes reinforced the stereotypes instead of demolishing them" (p. 173).

The choice of whether to send a violently disturbed adolescent to detention or to the hospital is often made by police, probation officers, and judges as well as emergency room physicians. Thus the medical and the law enforcement professions share in perpetuating the segregation of white and black violently disturbed adolescents.

Our clinical and epidemiological findings indicate clearly that many seriously psychiatrically disturbed, aggressive black adolescents are being channeled to correctional facilities while their equally aggressive white counterparts are directed toward psychiatric treatment facilities. As a result of this practice, correctional facilities in the United States are being asked to function as the mental hospitals of the lower socioeconomic class black population. Conversely, it is likely (in view of the behaviors documented in the records of hospitalized white adolescents) that some of our state hospitals are required to function as jails for the disturbed, aggressive, lower socioeconomic class white population. The failure of white mental health professionals to recognize, diagnose, and treat psychopathology in their black adolescent clients may explain in great measure the fact that our prisons and reform schools are becoming increasingly populated by members of minority groups.

BRIEF COMMUNICATIONS

Disulfiram Encephalopathy as a Cause of the Catatonia Syndrome

BY WILLIAM W. WEDDINGTON, JR., M.D., ROBERT C. MARKS, M.D., J. PETER VERGHESE, M.D.

The authors describe a case of the catatonia syndrome associated with disulfiram therapy. Although useful in the management of chronic alcoholism, disulfiram is being increasingly associated with a wide spectrum of side effects and untoward medical sequelae, which now include catatonia. The authors note that catatonia is a clinical syndrome associated with multiple medical conditions as well as psychiatric disorders.

Disulfiram became a popular drug in the management of chronic alcoholism after 1948, when Hald and associates (1) noted that disulfiram interfered with the metabolism of ethanol by blocking liver aldehyde dehydrogenase. The buildup of high blood levels of acetaldehyde in an individual who ingests both disulfiram and alcohol leads to the toxic reaction of vasodilation, hypotension, tachycardia, vomiting, headache, and sometimes death. Acute organic brain syndrome is a reported side effect of disulfiram taken without alcohol (2). Liddon and Satran (3) reviewed 52 cases of disulfiram-associated psychotic reactions and noted a wide spectrum of clinical symptoms, including confusion, anxiety states, depression, mania, paranoia, and frank convulsions.

Other investigators have pointed out the possible serious medical sequelae of extended disulfiram use. Plotnick (4) and Yodaiken (5) warned that workers who are exposed to ethylene dibromide (used in fuels and insectides) and are receiving disulfiram are at considerable risk for developing malignant tumors. Rainey (6) proposed that carbon disulfide may be the metabolite of disulfiram that is responsible for the drug's side effects and that alcoholic individuals receiving as little as 125 mg/day of disulfiram may have a four times greater risk of developing arteriosclerotic cardiovascular disease than do control subjects. However, Faiman and associates (7) question Rainey's assumptions and suggest that his conclusions are speculative. Lake and associates (8) noted small but significant increases in plasma norepinephrine and blood pressure in hospitalized alcoholic patients receiving 500 mg/day of disulfiram.

Gottesfeld and associates (9) reported what is to our knowledge the first case of acute catatonia associated with disulfiram therapy; they and others (10, 11) also have reported schizophrenic-like symptoms in other patients taking disulfiram. Reisberg (12) recently reported a second case of disulfiram-associated catatonia.

Catatonia was first described by Kahlbaum in 1874 (13) as a "symptom complex" consisting of negativism, catalepsy, mutism, stereotypies, and verbigeration (stereotyped language). Kahlbaum considered catatonia to be the manifestation of pathological brain structure. Kraepelin (14) included excited and retarded forms of catatonia as subtypes of the mental illness that he named "dementia praecox." Bleuler (15) redefined and expanded on Kraepelin's systematic classification of the psychoses and introduced the term "schizophrenia." Bleuler maintained catatonia as a schizophrenic subtype. Both Kraepelin and Bleuler taught that catatonic signs could be secondary to other conditions and were not exclusive symptoms of dementia praecox or schizophrenia, although Kraepelin

may have overvalued catatonia as evidence of a functional psychosis (16). Gelenberg (17) pointed out that the catatonic syndrome has come to be associated with schizophrenia in teaching and clinical practice since Kraepelin and that other causes of the syndrome have been understated. He noted that catatonia may also be a manifestation of neurological disorders involving focal lesions in the basal ganglia, limbic system, temporal lobes, and diencephalon. Drugs that have been documented to induce catatonic reactions include aspirin, ACTH (17), the neuroleptics (18, 19), and now disulfiram. Other causes of catatonia are infections and metabolic and toxic conditions, as well as such psychiatric disorders as schizophrenia, manic-depressive illness, and the neuroses (17).

Abrams and Taylor (20) studied prospectively 55 psychiatric patients who exhibited one or more of the following catatonic motor signs: mutism, stereotypy, posturing, catalepsy, automatic obedience, negativism, echolalia/echopraxia, and stupor; only 4 patients (7%) satisfied criteria for schizophrenia, 39 (71%) had an affective illness, 9 (16%) had epilepsy, encephalitis, or drug-induced or toxic psychoses, and 3 patients (5%) had a reactive psychosis. Interestingly, two-thirds of the patients showed marked improvement or full remission after short-term treatment. Other studies have demonstrated that 16%–19% (21, 22) of 250 catatonic patients qualified for the diagnosis of a primary affective disorder, and 13.5%–28% (23–25) of manic patients exhibited clinical signs of catatonia. The catatonic signs were not predictive of outcome in treated and untreated patients. In this paper, we will describe a third patient who manifested catatonic symptoms as part of a disulfiram-induced encephalopathy.

CASE REPORT

Mr. A, a 25-year-old engineer, had a 9-year history of alcohol abuse. At the insistence of his work supervisor and his wife, he entered an inpatient alcoholic treatment unit several years ago. He was discharged 1 month later and maintained on 250 mg/day of disulfiram, which had been started about 2 weeks after he entered the treatment unit. Mr. A refrained from alcohol use and within 1 month after his discharge was functioning well at work and home. About 10 days later a marked change in Mr. A's behavior occurred. He became quiet and withdrawn and began to complain of diminishing memory, headaches, and dizziness. Five days later (the day before his admission to a local community hospital) Ms. A noticed that her husband was staring for long periods, apparently awake but not responsive; he was intermittently agitated. Ms. A encouraged Mr. A to stop taking disulfiram and arranged for his immediate admission.

On the day that Mr. A was admitted to the hospital, Ms. A stated that in spite of the success of her husband's alcoholic treatment program, she thought he had been "worried a lot." She also reported that Mr. A's younger sister was a chronic schizophrenic. No other family members were known to have mental illness.

During his stay in the hospital Mr. A was intermittently withdrawn and excited. Results of his physical examination were unremarkable except for hypertension (blood pressure=200/110). Laboratory results were entirely within normal limits except for a serum sodium of 133 mEq/liter, hemoglobin of 13.8 g/100 ml, and ECGs showing nonspecific T-wave changes. Serum alcohol levels were negative.

On admission, Mr. A was given 100 mg i.m. of chlordiazepoxide immediately and 50 mg b.i.d. orally, in addition to thiamine, 100 mg b.i.d. orally. There was no immediate change in his behavior. He was negativistic and occasionally self-mutilating and sat immobile staring at a television set for hours. After 5 days of hospitalization and no clarification of diagnosis or evidence of improvement, Mr. A was transferred to our medical center for further evaluation.

At the time of the transfer, Mr. A was perseverating, disoriented to time and place, restless, and showed a profound memory loss, both recent and remote. His general physical examination was normal except for injected conjunctivae. A neurological examination was unremarkable except for the marked mental status changes already noted. A traumatic lumbar puncture was performed: the opening pressure was 120 mm water; there were 6 lymphocytes and 5000 red cells per mm^3; and the spinal fluid contained 53 mg/100 ml of protein and 42 mg/100 ml of glucose (serum glucose, 79 mg/100 ml). Assays for neurotropic viral antibodies had negative results.

During the next 5 days, Mr. A remained intermittently agitated and withdrawn. He pulled out his intravenous tube, exhibited posturing of his arms, and was negativistic, refusing to eat or have vital signs taken. There were no focal neurological findings. On the 4th day after his transfer Mr. A had an EEG that showed "diffuse disorganization and disruption of activity . . . consistent with a diffuse gray and white matter encephalopathic process." On the 5th day a neuroleptic was administered to control his agitation (75 mg i.m. of chlorpromazine and 25 mg orally q.i.d.)

A psychiatric evaluation on the 6th day after his transfer revealed that Mr. A was awake, staring, and with his arm raised in a fixed position. He was not responsive to questioning, his affect was flat, and he resisted passive movements of his extremities and neck. His orientation, thought process, judgment, and insight could not be further evaluated. The psychiatrists recommended that chlorpromazine be discontinued and haloperidol 2.5 mg/hour i.m. as needed be started; Mr. A received approximately 10 mg/day of haloperidol for the next 2 weeks. Mr. A continued to exhibit combativeness, negativism, posturing, withdrawal, mutism, and staring. No focal neurological signs appeared. A second EEG on the 7th day on the neurological ward showed a pattern "entirely monotone without well formed dominant patterns." A second lumbar puncture performed on his 8th day was unremarkable.

After 12 days Mr. A began to improve. He was less agitated and took oral fluids more easily. On his 13th day the third EEG remained abnormal; there was intermittent slowing over both hemispheres with asymetrical activity and the suggestion of periodic complexes, particularly over the right hemisphere, consistent with improvement. Two days later Mr. A was able to talk and respond appropriately to simple questions and commands. Nonetheless, he continued to sit

immobile most of the time and had an expressionless face. A CT scan 1 day later was normal, and haloperidol treatment was discontinued 2 days afterward because of Mr. A's improvement.

By his 21st day on the neurological ward Mr. A was fully oriented. He continued to improve and was discharged 5 days later. Extensive psychometric testing before discharge suggested a mild organic brain syndrome. When he returned to the clinic 10 days after discharge, no detectable deficits were observed. Mr. A returned to the alcoholic treatment program but no longer took disulfiram.

In summary, after Mr. A began disulfiram treatment, he experienced no detectable side effects from the medication for 2 months. When he began experiencing some dysphoria followed rapidly by changes in sensorium and behavior, disulfiram treatment was stopped and he became intermittently withdrawn and excited; 10 days after stopping disulfiram, Mr. A. exhibited signs of catatonia that persisted for 1 week and then resolved over the next 2 weeks. Follow-up over 2 years has demonstrated a consistently normal mental status exam, although he has had several episodic drinking binges.

COMMENT

We have described a patient known to be taking disulfiram and successfully abstaining from alcohol who developed a catatonic syndrome manifested by mutism, negativism, stereotypy, staring, and combativeness. The syndrome quickly reversed to normal behavior after disulfiram was discontinued. Given the patient's positive family history of mental illness, it is possible that the patient is genetically vulnerable to a schizophreniform illness, which may have been exacerbated by disulfiram (11). The increased susceptibility of schizophrenic individuals to the untoward side effects of disulfiram may stem from disulfiram's property as a known inhibitor of dopamine β-hydroxylase (26). Ewing and associates (27) hypothesized that disulfiram might be able to provoke a psychosis by means of blocking the production of norepinephrine from dopamine.

Disulfiram is an important and useful modality in the management of chronic alcoholism, a disease with considerable morbidity and mortality. However, clinicians should now add catatonia to the list of toxic conditions associated with disulfiram and carefully monitor disulfiram-treated alcoholic individuals for behavioral changes, particularly during the early treatment period and in patients who have a positive family history of psychiatric illness. Catatonia remains a clinical syndrome that is associated with multiple medical conditions as well as psychiatric disorders.

Dialysis of Schizophrenic Patients: A Double-Blind Study

BY JOSE A. DIAZ-BUXO, MD., JOHN A. CAUDLE, M.D., JOE T. CHANDLER, M.D., CHARLES D. FARMER, M.D., AND WILLIAM D. HOLBROOK, M.D.

The authors designed a double-blind hemodialysis protocol consisting of hemodialysis or sham dialysis twice weekly for 10 weeks, respectively. Four patients were carefully selected and evaluated clinically and on the Clinical Global Impression Scale. Three did not show any signs of improvement, and one patient demonstrated questionable improvement but decompensated after 12 additional weeks of hemodialysis. This preliminary study does not confirm the hypothesis that hemodialysis is effective in controlling psychotic symptoms. The authors consider other possibly beneficial treatments for schizophrenia.

Schizophrenia is characterized by progressive deterioration of affect, mentation, and conduct and has considerable negative socioeconomic impact. The report by Wagemaker and Cade (1) claiming a remarkable cure in 17 of 24 patients has aroused tremendous interest in the potential benefits of dialysis in the treatment of this disease. Despite universal enthusiasm, skeptics have pointed out the possible flaws of these studies (2): 1) there could be beneficial effects from the distress of undergoing dialysis in such impressive and strange surroundings, with venipunctures, extracorporeal circulation, and sophisticated monitoring systems; 2) the placebo effect or withdrawal of current drug therapy could cause improvement; and 3) the additional attention paid to these patients and the ancillary services given (occupational and recreational therapy) could be responsible for the improvement (3).

In an attempt to further characterize the potential benefits of dialysis in the treatment of schizophrenia, we designed and completed a preliminary double-blind study at Charlotte Memorial Hospital and Medical Center.

Received July 23, 1979; revised Dec. 17, 1979; accepted April 4, 1980.

From the Nephrology Division (Drs. Diaz-Buxo, Chandler, and Farmer), and the Department of Psychiatry (Drs. Caudle and Holbrook), Charlotte Memorial Hospital and Medical Center, Charlotte, N.C.

METHOD

We selected four patients who had been diagnosed as having chronic schizophrenia by Bleuler's primary symptoms of looseness of association, inappropriateness of affect, and the presence of autistic logic. We did not feel that the thought disorder was secondary to their disorder of affect. Delusions and hallucinations, although present in most, were considered secondary symptoms. All patients had suffered a chronic thought disorder and disorder of affect and had been unresponsive to antipsychotic medications for at least 1 year. At any time during the study, if the patient was doing well antipsychotic medications could be reduced or stopped; however, if the patient worsened the medication could be increased and if necessary the patient could be hospitalized, with every effort made to continue the scheduled dialysis.

Before initiation of dialysis, all candidates were interviewed by one or both principal investigators (J.A.D.-B. and J.A.C.) and the nature, risks, and potential benefits of the procedure were discussed. If the investigators felt the candidate was unable to make a decision in his best interest, written consent was obtained from his guardian or first of kin. A pertinent history was taken and a physical examination was performed on each candidate and routine laboratory evaluations including hemoglobin, white blood cell count, hematocrit, serum sodium, potassium chloride, carbon dioxide, urea nitrogen, creatinine, alkaline phosphatase, CPK, SGOT, calcium, and phosphorus determinations were made before dialysis and monthly thereafter. An internal arteriovenous fistula was created in the nondominant upper extremity 4–6 weeks before initiation of therapy. All patients were evaluated on the Clinical Global Impression scale (CGI) and by extensive psychiatric interviews and reevaluated every 1–2 weeks during the study if possible.

Dialysis was provided with the Travenol RSP delivery system and a parallel flow, 85 M^2, 11 micra Cuprophane membrane dialyzer. Blood flows were maintained at 200 cc/minute and dialysate flows at 500 cc/minute. Each dialysis session lasted 4 hours.

During the control period (sham dialysis), the same equipment was used for the same length of time but only blood and not the dialysate was circulated, creating a situation of only extracorporeal circulation through the dialyzer. In order to keep the study blind to both patients and investigators, the dialysate lines were covered with dark material. Only the dialysis nurse was aware whether the patient was on real or sham dialysis.

Cards were drawn by the dialysis nurse for selection of treatment versus sham dialysis. The study protocol consisted of two phases: phase A, during which the patient received hemodialysis treatments, and phase B, during which the patient received sham dialysis. Each phase lasted 10 weeks, during which time hemodialysis or sham dialysis was administered twice weekly. After the subject had completed both phases of 20 weeks of study, the code was broken; if hemodialysis was considered beneficial, the patient was assigned to a maintenance phase (phase C) during which hemodialysis was administered for 4 hours weekly or as dictated by the patient's clinical status at the time.

The results were assessed after 20 weeks of study according to the data collected during the weekly CGIS determinations and individual psychiatric interviews.

CASE REPORTS

Case 1. Mr. A, a 45-year-old man, was admitted to the program while taking chlorpromazine, 100 mg q.i.d., amitriptyline, 50 mg q.i.d., and hydroxyline pamoate, 50 mg q.i.d. He had been hostile, paranoid, depressed, and exhibited suicidal thoughts. He had visual hallucinations of a headless man. The initial diagnosis was paranoid schizophrenia. Mr. A gradually became very depressed and required 8 ECT treatments every 3 months. He had received a total of over 150 ECT treatments in the 5-year period before he joined this study.

During the first 20 dialysis treatments Mr. A stopped hearing voices and was not depressed, and all his medications were stopped. During the second 20 dialysis treatments he relapsed and became very depressed and suicidal in spite of renewed medications. Eight ECT treatments between the 27th and 35th dialysis treatments were given because of suicide attempts. Once the code was broken, we noted that Mr. A had done much better during sham dialysis and had relapsed during real dialysis.

Case 2. Ms. B, a 31-year-old woman, had an 18-month history of recurrent episodes of psychosis characterized by auditory hallucinations, delusions, autistic thinking, inappropriate affect, religiosity, and grandiosity. At times she would become quite withdrawn, depressed, and noncommunicative. No response to ECT had been observed. Ms. B was selected for dialysis therapy and after 4 treatments her psychotic symptoms worsened and she had to be rehospitalized. At that time she was placed on thiothixene, 80 mg/day. Dialysis was continued and the thiothixene was gradually reduced to 10 mg t.i.d. during the second 20 dialysis treatments. She was not evaluated on the Clinical Global Impression Scale, but the psychiatric examiner (J.A.C.) believed that Ms. B did better during the second series of 20 dialysis treatments. The code revealed that Ms. B had the real dialysis during the first 20 treatments.

Case 3. Mr. C, a 36-year-old man with an 11-year history of schizophrenia, had been severely disturbed for 3 years, with aggressive outbursts, a very severe sleep disturbance, auditory hallucinations, grandiose ideas, and an inability to relate to others. Antipsychotic medication had been ineffective, and he had been unable to work for the 8 months before he entered the dialysis study. At the time he started dialysis he was taking fluphenazine, 5 mg h.s.

After the code was broken, we found that Mr. C had real dialysis during the first 20 treatments. At that time, he seemed to improve, and we reduced his fluphenazine to 2.5 mg h.s. However, during the sham dialysis he showed marked deterioration, and we increased fluphenazine to 5 mg h.s. Since Mr. C seemed to have done better on real than sham dialysis, he was restarted on real dialysis once a week. He seemed to slowly improve on real dialysis and became less hostile and delusional, although he continued to hear voices. He was able to relate and to control his psychotic symptoms. He remained on fluphenazine, 5 mg h.s. After 6 hemodialytic treatments Mr. C returned to work, although he continued to have psychotic symptoms that he could control. Within 48 hours Mr. C relapsed into a markedly psychotic state; he was hostile and belligerent, was out of touch with reality, heard voices once more, and was unable to function. He was restarted on fluphenazine but did not improve and had to stop working. After 12 dialysis treatments (1 per week), Mr. C was dropped from the study at his own request. We believe that he suffers from grandiose parancid schizophrenia; during the time that he seemed to get better he was not working and the usual life stresses that he had lived with were diminished. During the rest of the treatment, he showed signs of psychosis, and during phase C he relapsed into a severely psychotic state.

Case 4. Mr. D, a 35-year-old man, had an 18-year history of mental illness manifested by inappropriate affect, loose associations, and paranoid thinking that was primarily focused on his father. He had flat affect and significant anxiety and was not able to go out among people. We believed he was suffering from chronic undifferentiated schizophrenia. When he entered the treatment program, he was receiving thioridazine, 150 mg h.s. After 24 dialysis treatments the psychiatric examiner (J.A.C.) and the examiner in charge of the dialysis unit (J.A.D.-B.) communicated and the code was broken. Mr. D had been on real dialysis for the first 20 treatments and had not improved.

DISCUSSION

Although hemodialysis was first reported as a treatment for schizophrenia in 1960 by Feer and associates (4), the studies were uncontrolled and inconclusive and little attention was generated. The work of Wagemaker and Cade (1), revealing dramatic improvement in a large series of patients, has engendered new enthusiasm, but their study was also uncontrolled. The

possible identification of an abnormal polypeptide in schizophrenic patients that is recovered in high concentrations in the dialysate of these patients (5) may be of greater significance than the improvement noted by Wagemaker and Cade; however, these findings have not been duplicated. The mechanism by which hemodialysis removed this potential toxin is difficult to explain with our available understanding of membrane dynamics and renal physiology. Port and associates (6) and Kolff (2) have analyzed these problems in the light of our present knowledge and calculated the hypothetical clearance of endorphins by different modalities of therapy. It seems likely that if indeed abnormal endorphin accumulation is responsible for the symptoms of schizophrenia, other modalities of therapy such as diafiltration or peritoneal dialysis would be more effective than hemodialysis.

Our study, which is preliminary and very limited in its scope, was not intended to deter others from looking at this potentially important therapeutic and diagnostic tool. However, our results must be considered definitely negative, which emphasizes the importance of controlled and double-blind protocols if scientific conclusions are to be derived from such a costly and potentially hazardous study. We must also diagnose the type of psychosis of the individuals treated and report our findings as precisely as possible. If dialysis indeed ameliorates or cures psychotic symptoms, further studies should be funded that may lead to a better understanding of and therapy for schizophrenia.

Cinderella Syndrome: Children Who Simulate Neglect

BY JEAN GOODWIN, M.D., M.P.H., CATHERINE G. CAUTHORNE, PH.D., AND RICHARD T. RADA, M.D.

The authors describe three adopted girls, aged 9 and 10, who falsely alleged that their adoptive mothers dressed them in rags, made them do all the chores, and favored their stepsiblings. Underlying these false accusations of abuse was a history that included 1) actual abuse of the child in a previous placement, 2) early loss of a mothering figure, and 3) emotional abuse in the adoptive home. Professionals involved in child protection need to recognize this syndrome because intensive family therapy and temporary placement of the child outside the home are required in all cases. The child's false accusation of abuse is a cry for help and should not be dismissed as a manipulative fabrication.

When professionals responsible for child protection discover that a child has exaggerated, fabricated, or simulated abuse, they tend to respond by simply closing the case. However, we have previously shown that false accusations of sexual abuse are often a child's way of calling for help in a family situation that has become desperate for other reasons (1). This report describes a similar pattern in false accusations of child neglect. In the three cases we report, the child's false accusation of neglect called attention to underlying family dysfunction that did require the intervention of a child protection agency.

In these three cases of simulated neglect, adopted girls had complaints remarkably like those of the fairy-tale heroine Cinderella. Each falsely alleged that her stepmother dressed her in rags, made her do all the chores, and showed preference for her stepsiblings. All three girls had been adopted by relatives after suffering the traumatic death of an early mothering figure.

Presented at the 133rd annual meeting of the American Psychiatric Association, San Francisco, Calif., May 3-9, 1980. Received Dec. 17, 1979; accepted March 18, 1980.

From the Department of Psychiatry, University of New Mexico School of Medicine (Drs. Goodwin and Rada), and the Indian Children's Project, All-Indian Pueblo Council, Albuquerque, N.M. (Dr. Cauthorne).

The children's Cinderella-like accusations functioned at several levels as a cry for help: 1) they were being emotionally abused and probably would have been physically abused had their false accusations not led to the involvement of a child protection agency and their temporary removal from the home; 2) they had never resolved experiences of abuse and abandonment that occurred before adoption; and 3) all three stepmothers had been abused as children and needed to integrate those past experiences before they could fully accept their stepdaughters. In addition, the Cinderella tale mapped inner conflicts that these children needed to explore in treatment. All of the families were hostile to psychotherapy. It was only under pressure of the legally mandated investigation triggered by the child's false accusation of neglect that these families allowed the troubled child to receive needed treatment.

CASE REPORTS

Case 1. Adele, a 9-year-old girl, was referred to a child protection agency when a policeman found her wandering outside school clad only in an undershirt and panties. She explained that because she had been unable to finish her chores at home, her adoptive mother had locked her out of the house. She said her adoptive parents often took her stepsiblings on outings, leaving her at home to do all the chores. A family interview established that Adele had taken off her own clothes and hidden them.

Adele's biological mother died when Adele was 1 year old. Adele was then placed with another relative, an alcoholic woman who neglected and physically and sexually abused her. This woman died when Adele was 6; she was then adopted by her current parents. Her adoptive father was also her uncle.

Adele's adoptive father, who held two jobs, tended to be distant and aloof. His wife, herself sexually abused and brutally beaten as a child, was an anxious woman with many compulsive rituals who bitterly resented Adele's uncontrollable behavior. The stepsiblings became angry with Adele for upsetting their mother. Adele said she wanted to be a member of the family and to get all her chores done.

The adoptive parents decided to voluntarily place Adele in foster care while she received therapy. They refused family therapy, but the mother agreed to participate in joint sessions with Adele's therapist. After 4 months Adele was reintegrated into the adoptive family.

Case 2. Betty, a 9-year-old girl, was referred by the school because she came to class in shabby clothes and without

shoes. Betty said her adoptive mother had thrown away her shoes as punishment for not cleaning under the bed. A family interview established that Betty had changed into shabby clothes on her way to school.

Betty had been adopted into this family at age 6. Her adoptive mother was her biological mother. Because Betty's mother was an unmarried schoolgirl when Betty was born, Betty was raised from birth by a friend of her mother, who was killed in an auto accident when Betty was 6. This foster mother had been overprotective and indulgent, keeping Betty on a bottle until age 4. After the foster mother's death, the girl's biological mother forcibly removed her from the foster home, not telling the child until a year later that she was her biological mother. Betty had many questions about her biological father, but her mother refused to speak of him.

The mother's present husband was a volatile man who refused to become involved with Betty. The mother felt frustrated about disciplining Betty, saying that the child responded to reprimands by tearing up clothes and toys. Betty's adoptive mother had been the victim of sadistic abuse as a child. The stepsiblings resented Betty and physically abused her by locking her in the doghouse and feeding her dog food. Betty had frequent stomachaches, had one episode of hysterical paralysis, and daydreamed that a race car driver would come and rescue her. After a year of play therapy Betty was able to be in the home only on weekends. Her adoptive parents still refused to become involved in her treatment and finally agreed to place Betty permanently with other relatives.

Case 3. Carol, a 10-year-old girl, was referred to a child protective agency by a passerby. Carol had run up to this man and told him that her adoptive mother had kicked her and was keeping her home from school to do all the household chores. Carol used terms such as "child sexual abuse" in describing her problems. A family interview revealed that the bruise Carol offered as evidence of being kicked had been sustained in a baseball accident and that she had refused to go to school because she had not been given the part of the princess in a school play. At age 9 Carol had claimed that her adoptive mother was trying to drown her in the bathtub. That complaint had been dismissed as fiction, and therapy was not offered.

Before her adoption, Carol had been an abused child raised in a psychotic family situation. Carol's psychotic mother had abused her by tying her hands and forcing her head into the toilet. Carol first lived with her adoptive parents at ages 5 and 6 while her mother, a relative of the adoptive father, was psychiatrically hospitalized. At age 7 Carol returned to live with her mother, who had remarried. The new stepfather began a sexual relationship with Carol. Within a year Carol's mother committed suicide.

When Carol was 9 her current parents adopted her; their only biological child, a blind and severely retarded son, had been institutionalized shortly before. Soon after her adoption, Carol had one episode of hysterical blindness.

The adoptive father held two jobs. He was ashamed of the mental illness of his relative, Carol's natural mother, and refused to allow Carol to speak of her. The adoptive mother had been sadistically beaten as a child by her mother and had been sexually abused by her father, but never complained about these incidents because she feared that she would not be believed. She felt defeated by Carol, something she denied having felt with her severely handicapped son, and she spanked Carol hard enough at times to leave bruises. Carol was not certain that her natural mother was dead and daydreamed about returning to her.

Carol was placed in a foster home. The foster mother complained that Carol refused to go to school or to do chores and that she made false accusations against her foster siblings. After 3 months of family therapy Carol was able to be with her adoptive parents on weekends.

DISCUSSION

These three cases were the only documented instances of simulated neglect seen over a 3-year period in a child protection agency that screens 150 complaints of neglect each month. Since the children were treated by different therapists, their remarkable similarities were not recognized until a systematic review of the agency's cases.

Child protection workers are understandably reluctant to make the judgment that a child is lying about parental abuse. One case report (2) described a 3-year-old whose allegation that his mother beat and burned him was dismissed as a false accusation planted by his father, who was estranged from the mother. Four months later this child was beaten to death by his mother. The cases reported here make the additional point that even if the worker is correct in judging a child's accusation to be a lie, other kinds of abuse may still be occurring in the home.

These three cases are remarkably similar and appear to represent a specific syndrome. All three children were 9- or 10-year-old girls who had entered their adoptive homes at about age 6. Each had experienced the traumatic death of an earlier mothering figure before adoption. Two of the girls had been sexually abused in their earlier homes; two had developed hysterical symptoms after adoption (one paralysis and the other blindness). The adoptive fathers were emotionally distant and unavailable to the children. The adoptive mothers had been severely abused as children and were appalled at being regarded as "bad" mothers, in part because that was how they viewed their own mothers. There was intense rivalry with stepsiblings in all cases. Betty was physically abused by her stepsiblings, and Carol developed the symptom of blindness, which mimicked the handicap of her stepbrother (3).

The false accusations made by these girls closely resemble the complaints of the fairy-tale heroine Cinderella. There is one report (4) of a 5-year-old girl who briefly took on the role of Cinderella, complaining that her mother made her do the hardest chores, made her sleep in the ashes, and favored her younger sister. The three girls reported here had similar complaints, but they were unable to deal with their grievances in fantasy or in play; instead, they presented them as realities.

In the original fairy tale, Cinderella's grief for her dead mother is a central issue. Early Italian versions of the tale described an incestuous relationship between Cinderella and her father. The normal rivalry of the

oedipal-age girl with her mother is intensified by actual incest with the father, and, should the mother die at the height of this intense competitive conflict, the child may experience the unconscious fear that she caused the mother's death (5). The girl must blot out all negative feelings about the mother in order to avoid intolerable guilt about her mother's death. In the Cinderella story, these negative feelings were displaced and projected onto the stepmother, and the dead mother was idealized.

Sibling rivalry is particularly intense for the Cinderella child, partly because she feels that her parents prefer her siblings to someone guilty of incest and murder and partly because she may provoke victimization by her siblings to punish herself and assuage her guilt. The therapeutic solution prescribed in the fairy tale was for Cinderella to complete the grief work for her mother—in the story she watered a tree on her mother's grave with her tears daily—and to accept the tasks requested both by the "bad" stepmother and the "good" fairy godmother. This acceptance of chores is a nucleus for the identification with the mother that must supplant rivalry.

Treatment of these cases is complex. Strategies include family therapy, individual therapy for the adoptive parents, and play therapy for the children. Family therapy defines the situation as a family problem and resists the family's effort to find a scapegoat. In our cases, individual play therapy focused on helping the child to mourn the idealized dead mother and to give up fantasies of reunion with her. It was critical for the therapist to visit the child in her home—as did the prince in the fairy tale. These children tended to shamefully conceal from the therapist the rejecting and lacerating family battles that constituted the actual abuse; the false accusation was a face-saving version of the actual situation revealed in the home visit.

The therapist had to monitor the family situation carefully throughout treatment because premature therapeutic interventions tended to trigger new cycles of simulated abuse. When the child felt rejected or blamed because of a therapeutic confrontation, she would provoke or invent a situation in which she felt unfairly abused by the family. This process assuaged the child's guilt and renewed her hopes that she might be rescued by a perfect, fantasized family, perhaps with the therapist. However, this acting out also provoked actual rejection and abuse by the outraged adoptive family. Ultimately, the "wicked stepmother" had to be brought into the child's treatment in order to break this cycle.

Therapy with the adoptive parents focused on their unresolved feelings about the child's lost parent and about their own parents. Two of the adoptive fathers—Carol's and Adele's—felt intense rage and shame about their psychotic female relatives who had abused these girls and thus would not allow the girls to speak of these mother-figures. Similarly, the adoptive mothers needed help in resolving their anger and guilt about their own abusive mothers and childhood experiences of sexual abuse. The adoptive mothers' guilt about childhood incest fostered their identification with the girls' guilt-ridden attempts to degrade themselves as well as their mothers. They seemed unconsciously gratified that the adoptive daughters were voicing complaints that they themselves had never dared to make; at the same time, the false accusations freed these mothers from the danger of surpassing their own mothers by being "good," nonabusing mothers (6). As the adoptive mothers' fear and rage lessened, they were better able to consistently enforce the performance of chores and to allow the girls to identify with them in more positive ways.

Although they are rare, cases involving simulated child abuse should be actively evaluated by professionals. In each of these three cases of simulated abuse, actual physical abuse or neglect was subsequently uncovered. It is possible that more severe abuse would have occurred had the child's simulated abuse not brought her family to professional attention.

Sex and the Boards

BY MARC H. JACOBS, M.D., AND LOMA K. FLOWERS, M.D.

In 1978 a questionnaire on the functioning of the American Board of Psychiatry and Neurology was mailed to a sample of APA members. The authors present the significant differences in responses between men and women psychiatrists. A higher percentage of women than men were among those who had experienced stress from the time and effort involved in taking the Board examinations and from fear of the oral examination; 45% of the women respondents who had received certification had done so since 1975, versus 23% for the men. The authors discuss possible explanations for the sex differences, including role strain, and suggest greater flexibility in where, when, and how Board examinations can be taken.

In 1976 the membership of APA approved by a wide margin two referenda concerning the American Board of Psychiatry and Neurology (ABPN). Our paper results from the referendum that called for the appointment of a task force, one of whose charges was to "actively seek and summarize the view of the APA membership with regard to ABPN functioning." The questionnaire designed for this task generated an enormous number of data, and this paper explores those data which relate to the differences in views between men and women psychiatrists.

METHOD

The questionnaire (available on request from the authors) was divided into six sections: background information, factors inhibiting certification, certification policies, recommendations regarding certifying exams, personal experiences with the ABPN, and additional comments. The 66-item questionnaire was sent to a random sample of 4,800 APA members (20%). The return rate was 66%. Not every question was answered by all respondents, so there were variations in the sample size for individual questions. All questions were cross-tabulated with the question "What is your sex?" and the data were examined by chi-square analyses to determine the significance of differences between responses of men and women psychiatrists. Differences were considered significant at the .05 level.

RESULTS

Background Information

Of the respondents, 88% (N=2,563) were men and 12% (N=351) were women. This is consistent with the current proportions of men and women psychiatrists in this country (personal communication from C. Robinowitz, C. Nadelson, M.T. Notman, 1979).

The training patterns reported by the two groups show that since 1960 the number of women completing their training has been steadily increasing: over half of the women respondents had completed their training since 1966, while the men were significantly more likely to have been trained before 1966 (see table 1). Twenty-five percent of the women were foreign medical graduates, which is significantly higher than the rate for men. They were also less likely to have been trained in Veterans Administration hospitals.

The background questions on Board certification revealed additional differences between the two groups. Women were less likely to have attempted any of the three stages of Board certification (application, written examination, and oral examination), but this trend is changing: 69.5% of the women respondents who had received certification had done so between 1966 and 1978; 45% had done so since 1975 (versus 55.3% and 23.2% for men) (see table 2). Ninety-five percent of the respondents who had participated in ABPN examinations were men, and far more men than women were certified in general psychiatry only. The two groups were equally likely to be certified in both general and child psychiatry or in both neurology and general psychiatry.

Factors Inhibiting Certification

In this section we found only one significant difference between the two groups: more women than

[b]Eleven questionnaires from women respondents did not contain this information.

men cited performance fear of both the oral and written examinations as reasons for not taking the Boards.

Certification Policies

Men and women respondents differed in their recommendations for changes in the Board certification policies. Slightly more women than men indicated that the system needs reworking. For example, a greater percentage of women thought that residency programs and the ABPN together should be responsible for certification and that there should be separate boards for neurology and psychiatry. More men felt that the ABPN alone should be responsible for certification. Men were also more opposed to the unpopular idea of having one board with separate testing procedures for psychiatry and neurology candidates.

A greater percentage of the women psychiatrists were among the majority favoring the following proposals: 1) ranking residency programs with respect to pass-fail rates, 2) making these pass-fail statistics available to potential residency applicants, and 3) offering the written certifying examination during residency. However, a greater percentage of the men were represented in the majority of respondents who agreed with the following statements in the questionnaire:

1. Residency programs should be given available knowledge profiles of their graduates.
2. Character and emotional stability should be used as eligibility criteria.
3. Certification should not be granted upon satisfactory completion of the residency alone.

Men were also more likely to support additional subspecialty certification, e.g., forensic, administrative, and adolescent psychiatry.

Recommendations Regarding the Certifying Exams

There was only one significant difference between the two groups in their recommendations on the examinations. More men than women supported the popular recommendation to retain both the oral and written examinations and the neurological sections of each.

Personal Experience with ABPN

The majority of those who had taken the Boards experienced stress from the time and effort involved and from fear of the oral examination. A higher percentage of women than men respondents were among this group. Similarly, a higher percentage of women were among the minority who were stressed by monetary cost, difficult logistics, insufficient time for completing the examination, and fear of the written exam. More women than men, however, felt that they had been advised adequately of the judgment criteria for the examination. There were no other significant differences.

DISCUSSION

It has been stated elsewhere (1, 2) that 40% of the women psychiatrists in this country are foreign medical graduates (FMGs), which is many more than in our study (25%). This may be because only APA members were sampled, or perhaps the number of U.S.-trained women is increasing fast enough to offset the increasingly large number of FMG women psychiatrists (1, 2).

The increase in the number of women psychiatrists found in our sample has been noted elsewhere (2). In addition, we noted a striking increase in the percentage of women certified in the period 1975–1978 compared with 1966–1974 or pre-1966. It is possible that this is a sampling error caused by the likelihood that women who were recently certified were more likely to return a questionnaire such as this. However, both of these findings may be accounted for in part by the influence of the women's movement and its encouragement of ambition and competition in women. For example, the APA Board of Trustees established a Committee on Women in 1974, the goals of which include promoting the academic involvement of women psychiatrists and providing emotional support systems for them.

That fewer women than men seek Board certification may be explained by our finding that women have a greater performance fear of the examination than men, despite similar success rates. This performance

fear, or anxiety, was described by Moulton (3) in her survey of men and women graduate analysts invited to make public speeches. She found that 50% of the women versus 20% of the men refused to speak in public. Cost in time and effort was not cited differently by the two groups.

More women than men indicated that the certification process needed reworking, perhaps because the women experienced more stress from the certification process. Horner (4, 5) found that women's actual performance worsened under competitive achievement conditions, while the reverse was true for men. These findings may suggest an inherent bias against women in an examination process that involves competition to determine achievement. Alternative testing procedures based on a less competitive model could be explored further.

The difference between the two groups' opinions regarding eligibility criteria and residency training program profiles could be the result of women being less willing to be judged, especially by men, who fill most residency training directorships and Board examiner positions. Alternatively, women psychiatrists may wish only the more general information made public, while the men want specific individual information made public. This is consistent with the different responses to competition seen in men and women.

The greater desire among men than women for more subspecialty certification may be related to Horner's finding (4, 5) that men's motivation for success increases under competitive achievement situations while women's decreases because they are caught in the double bind of being reluctant to be either a failure or a success. Some studies (6) suggest that men who achieve learn to expect rewards, whereas women learn to expect punishment. Also, as Applegarth (7) has noted, some women experience fears about sexual identity and unattractiveness to men, as well as guilt and primitive fears of retaliation and object loss, when being competitive or successful. Some successful women also regard their position as deviant (8, 9).

The women respondents' reports of greater stress from the cost in time and effort involved in the certification process were unrelated to the outcome of the exam. Role strain may be a partial explanation of the greater stress that women psychiatrists reported (10 and personal communication from N. Kaltreider, 1975). This possibility has been discussed elsewhere (11), and further research is necessary to confirm whether this was indeed the case with our women respondents. However, it has been suggested (12) that the demands of two disparate roles require more than twice the effort than would be necessary to perform either alone. This degree of role strain does not exist for men (9). It is interesting that the timing of the Board examination—two years after residency completion—coincides with the time that many men psychiatrists are most heavily invested in their careers, while many women psychiatrists are likely to have small children to care for. More data are needed to substantiate the hypothesis that the coincidence of timing is causally related to fewer women being Board certified.

The Board could reduce this role strain for women by providing greater flexibility in where, when, and how the examination can be taken. This could be done by allowing psychiatrists to take Board examinations over longer periods of time and by providing day care for children during the examination.

It is our hope that these data will be useful in providing the framework for a design for change, such as that envisioned by the APA membership when they passed the 1976 referenda on the American Board of Psychiatry and Neurology. The Board has already begun to institute some changes over the last three years. Our data show major differences in men's and women's responses to the Board certification process, which can be an important guide to any future changes in that process.

Transcendental Meditation Versus Muscle Relaxation: A Two-Year Follow-Up of a Controlled Experiment

BY DAVID C. ZUROFF, PH.D., AND J. CONRAD SCHWARZ, PH.D.

In this questionnaire survey the authors measured the outcome among 20 students randomly assigned to muscle relaxation training and 19 assigned to transcendental meditation at one year (the number of respondents in each group was 13 and 16, respectively) and two and one-half years (the number of respondents was 18 and 17, respectively). At both follow-ups there were no differences between the groups in frequency of practice or satisfaction. In both groups, less than 25% reported more than moderate satisfaction, and less than 20% practiced as much as once per week. Subjects' expectancies at nine weeks predicted their satisfaction and frequency of practice at two and one-half years. The authors conclude that although some subjects (15%–20%) do enjoy and continue to practice transcendental meditation, it is not universally beneficial.

Well-controlled studies of the short-term therapeutic effects of transcendental meditation have found it to have no more effect than placebo treatments (1), or at most to have moderate effects on trait anxiety (2). Related meditative techniques have not proven any better (3, 4). It is possible, however, that the wide range of benefits claimed by the technique's proponents are obtained only after long-term practice. The present study was designed to answer three questions concerning the long-term effects of meditation: 1) Do initiates in transcendental meditation perceive the practice to have been beneficial? 2) How high is the dropout rate after training? 3) Is it possible to predict who will continue to practice and benefit from meditation?

METHOD

The 60 subjects in the original study (2) were students from an introductory psychology course who volunteered with the understanding that they would be randomly assigned to receive training in either transcendental meditation or muscle relaxation, or to a no-treatment control group. All procedures were carefully explained before subjects consented to participate. Training sessions in transcendental meditation and muscle relaxation were conducted by, respectively, experienced initiators from the Student International Meditation Society and graduate students in psychology. The relaxation technique was Paul's version of Jacobsonian muscle relaxation (5), which involves alternately tensing and releasing the major muscle groups of the body. Training in relaxation was designed to have the same potent, nonspecific effects as training in meditation. The nine-week treatment period of the original study was dictated by the length of the students' semester. Information was collected concerning numerous variables that were thought to be potential predictors of response to treatment. Two follow-ups were conducted, the first one year after training and the second two and one-half years after training.

One year after training, subjects in the two treatment groups were mailed questionnaires asking them to describe their current frequencies of practice and to rate on a 5-point scale their overall satisfaction with their technique. This procedure was repeated two and one-half years after training; the questionnaire contained the additional question of whether there had been any intervals of a month or more during which the respondent had practiced more frequently than he or she did at present. The respondents were offered payment for returning the second questionnaire. Of the 19 meditation subjects, 16 returned the first questionnaire and 17 returned the second; of the 20 relaxation subjects, 13 returned the first questionnaire and 18 returned the second.

RESULTS

Perceived Benefit

At the one-year follow-up only 25% (N=4) of the meditation subjects and 15% (N=2) of the relaxation subjects described themselves as more than moder-

ately satisfied. At the follow-up after two and one-half years the proportions were 25% (N=4) and 22% (N=4), respectively. The differences between the groups were not statistically significant at either follow-up.

Frequency of Practice

As would be expected, frequencies of practice were low for both groups. Nineteen percent (N=3) of the meditation subjects and 15% (N=2) of the relaxation subjects were practicing once per week or more at one year. At two and one-half years 18% (N=3) of the meditation subjects and 11% (N=2) of the relaxation subjects were practicing that frequently. There were no statistically significant differences between the groups' frequencies of practice at either follow-up. More than half of the subjects in each group practiced less than once a month or not at all. Clearly, the large majority of both meditation and relaxation subjects essentially discontinued use of the techniques and felt that they had not been particularly beneficial.

Several interesting results emerged when the meditation group's frequencies of practice at one and two and one-half years were cross-tabulated. First, no subject who practiced infrequently (less than once per week) at one year was practicing frequently (once per week or more) at two and one-half years. On the other hand, every subject who practiced relatively frequently at one year continued to practice frequently at two and one-half years, and some increased their frequencies of practice. Each of the frequently practicing subjects described himself or herself as more than moderately satisfied at both follow-ups. These results imply that there are no "late bloomers" among initiates in transcendental meditation or returnees to the fold, but that there is a small group of 15%–20% who value meditation and continue to practice it with some regularity. These conclusions apply equally well to muscle relaxation trainees.

A third group of subjects—the occasional users—can be distinguished from the subjects who practiced regularly and those who virtually discontinued use of their technique. Seventeen percent (N=3) of the relaxation group and 29% (N=5) of the meditation group reported that there had been periods of a month or longer between the two follow-ups during which they practiced more frequently than they were practicing at two and one-half years.

Prediction of Response to Treatment

Multiple regression techniques were used to determine whether the measures of outcome (satisfaction and frequency of practice) could be predicted, given knowledge of the trainees' personality and behavioral characteristics. The potential predictors included trait anxiety, locus of control, maladjustment, drug and alcohol use, expectancies for benefits, attitudes of significant others, frequencies of practice during the nine-week treatment period, and experiences and heart rate while practicing. The measures employed have been described elsewhere (2).

Hierarchical multiple regression analyses (6) were performed, regressing the outcome variables on group membership (meditation versus relaxation), a potential predictor variable, and the product term representing the interaction of group and the potential predictor. The effect of each independent variable was tested against the error term from the regression equation in which that variable was the last one entered (Model I error [6]).

None of the interaction terms approached significance, indicating that the relationships between potential predictors and outcome variables were the same for meditation as for relaxation. Of the potential predictor variables, only the measures of expectancies for benefits were significantly related to the outcome variables. Expectancies measured after nine weeks of treatment were significantly related to both satisfaction ($t=3.5$, $df=31$, $p=.002$) and frequency of practice at 30 months ($t=2.8$, $df=32$, $p=.01$). Expectancies measured immediately after training were also significantly related to frequency of practice ($t=3.2$, $df=32$, $p=.04$) and tended to be related to satisfaction ($t=1.7$, $df=31$, $p=.11$). These results indicate that satisfaction with and frequency of practice of meditation and relaxation can be predicted from expectancies measured as early as nine weeks after training and, to a lesser extent, from expectancies immediately after training. The personality variables were not predictive of the measures of outcome; however, one must remember that the small sample provided only modest power to detect effects.

Finally, in a further search for correlates of continued treatment use, we conducted a series of one-way analyses of variance of the predictor variables, with subjects divided into relatively regular users of meditation or relaxation (once per week or more), dropouts (less than once per month), and occasional users. As might be expected, the dropouts had significantly lower expectancies after nine weeks of treatment than did the other groups ($F=6.5$, $df=1,32$, $p<.01$). It is of interest that the occasional users' scores on Rotter's locus of control scale (7) (mean=8.2) were more internal than those of the dropouts and regular users (mean=13.4) ($F=4.1$, $df=1,32$, $p<.05$).

DISCUSSION

The results of the two follow-up studies can be summarized as follows: 1) most subjects radically reduced their frequencies of practice of transcendental meditation or muscle relaxation within a year of training; 2) there was a small group of regular, satisfied users who continued to practice even two and one-half years after training; 3) there was another small group who typi-

cally did not practice but who occasionally used their techniques more regularly; 4) subjects' expectancies after nine weeks were related to outcome at two and one-half years; and 5) the occasional users tended to score as internals on Rotter's locus of control scale (7).

The three questions posed in the beginning of this article can now be given reasonably clear answers. First, most initiates in transcendental meditation did not perceive the technique as having been of major long-term benefit. Second, the long-term dropout rate was very high. This finding is consistent with other reports (1, 8, 9) of dropout rates of 50% or more. Third, one can predict treatment response by asking subjects whether they expect to benefit; however, no predictive personality or behavioral characteristics of the high expectancy-good response group were found. Although internality on the locus of control scale was unrelated to satisfaction or frequency of practice, it did predict a pattern of occasional use of the techniques.

These rather negative findings contrast sharply with the encouraging results obtained by earlier investigators (10). The difference may well be a consequence of the superior design of the present study, which was a longitudinal study of randomly assigned subjects. Many studies reporting positive results have been cross-sectional investigations of self-selected meditators with unknown dropout rates. Although the present results are based solely on self-report, one would expect that the true dropout rate was, if anything, higher than that reported, since biases in responding would be in the direction of underreporting discontinuation.

One may conclude from the results of the present study and the few other well-controlled studies that transcendental meditation is far less effective and satisfying than its proponents claim. After the initial surge of enthusiasm and sense of well-being pass, the modal initiate ceases to practice with any regularity and no longer feels great satisfaction with the technique. Professionals who are considering the use of meditation or relaxation in clinical settings may wish to use measures of expectancy to select the subset of patients who are likely to find the techniques helpful.

Neuroleptic Effect on Desipramine Steady-State Plasma Concentrations

BY J. CRAIG NELSON, M.D., AND PETER I. JATLOW, M.D.

The authors examined the effect of neuroleptic drugs on desipramine steady-state plasma concentration in 30 patients who received similar milligram per kilogram doses of desipramine. Fifteen of these patients also received a neuroleptic drug and had desipramine plasma levels twice that of the 15 patients who received desipramine alone. The authors discuss the implications of the magnitude of this difference for therapeutic response and incidence of side effects.

Tricyclic antidepressant drugs are often used in combination with antipsychotic agents to treat depressed schizophrenic patients (1) as well as patients with delusional depression (2). Use of this combination requires consideration not only of the therapeutic interaction of the two drugs but also of their pharmacokinetic interaction. Although Gram and coworkers (3–6) have extensively studied the effects of neuroleptic drugs on the elimination of single-dose nortriptyline and imipramine in man and rat, the clinical implications of this interaction during continued tricyclic administration are less clear.

Moody and associates (7) first described elevation of tricyclic plasma levels after chlorpromazine was administered to a patient receiving imipramine. Gram and associates (3, 4), using single dose ^{14}C-nortriptyline, demonstrated that perphenazine, haloperidol, and chlorpromazine increased the plasma concentration of nortriptyline and decreased the concentration of metabolites in plasma and urine. Subsequently, they demonstrated that perphenazine inhibited 2-hydroxylation of a single dose of ^{14}C-imipramine and that this effect was especially pronounced for desipramine (5, 6). Few studies have examined this effect on steady-state tricyclic levels. Olivier-Martin and associates (8) demonstrated that administration of levomepromazine resulted in a 30% rise in imipramine and a 200% rise in desipramine steady-state plasma concentrations. A similar effect on nortriptyline steady-state plasma concentration was recently noted by Vandel and associates (9) in patients receiving amitriptyline combined with a phenothiazine. Our report examines steady-state plasma concentrations of desipramine in patients being treated for depression with desipramine alone or in combination with an antipsychotic drug.

METHOD

Our sample consisted of 30 inpatients, 15 of whom had nondelusional unipolar depression, met Research Diagnostic Criteria (10) for major depressive episode, and were treated with desipramine alone (desipramine group); 15 delusional patients, all of whom were treated with a combination of desipramine and an antipsychotic agent (desipramine-antipsychotic group), met RDC for either major depressive episode, psychotic (N=10), or schizoaffective disorder (N=5). Although the desipramine group was slightly younger (table 1), the difference in mean age for the two groups was not significant. Furthermore, in this sample, the correlation for age and steady-state drug level was −.08. Desipramine levels were lower for the men; however, the sex ratio for the two groups was comparable. None of these 30 was receiving other drugs known to affect hepatic microsomal enzymes (e.g., barbiturates or methylphenidate).

Desipramine was administered orally in three divided doses at 10:00 a.m., 2:00 p.m., and 6:00 p.m. Dosage was calculated using a ratio of 2.5 mg/kg of body weight. The actual mean dosages received by the two groups, 2.55 and 2.50 mg/kg, were nearly identical. One-third the calculated dose was given the first day, two-thirds on the second day, and the full dose on the third day and thereafter. Plasma samples were drawn at 9:00 a.m. Heparinized glass syringes were used to avoid contact with rubber stoppers. Plasma concentrations of desipramine were determined in duplicate with a modification of a gas chromatographic

TABLE 1
Desipramine Plasma Concentrations and Patient Characteristics for 30 Depressed Patients

					Desipramine			
	Sex		Age (years)		Dose (mg/kg)		Plasma Level (ng/ml)[a]	
Group	M	F	Mean	SD	Mean	SD	Mean	SD
Desipramine alone (N=15)	5	10	38	13	2.55	0.18	110	81
Desipramine-antipsychotic (N=15)	4	11	48	18	2.50	0.22	255	115

[a]p<.002, Mann-Whitney rank order test.

nitrogen detector method previously described by Bailey and Jatlow (11). The average steady-state concentration was determined from three separate consecutive samplings after the patient had been on a constant dose for at least 10 days.

All 15 delusional patients received the antipsychotic drug first in order to facilitate clinical management and to prevent the possible exacerbation of psychosis by the antidepressant (12); 12 patients were treated with perphenazine (16–64 mg/day), 2 with haloperidol (6 and 20 mg/day), and 1 with thiothixene (12 mg/day). The dosage of the antipsychotic drug was determined depending on the needs of the patient.

RESULTS

The mean steady-state desipramine concentrations were 110 ng/ml for the desipramine group and 255 ng/ml for the desipramine-antipsychotic group (table 1). A nonparametric Mann-Whitney rank order test indicated the samples differed significantly ($p<.002$).

Although during the study no patient received other medications known to affect microsomal enzymes, 13 patients (3 in the desipramine group and 10 in the desipramine-antipsychotic group) received medications such as an antibiotic, a diuretic, a digitalis preparation, or benztropine mesylate. One of these patients had used barbiturates until 4 weeks before plasma levels were obtained. This prior use of a known enzyme inducer may explain the patient's unusually low plasma level (67 ng/ml) within the desipramine-antipsychotic group. Another of these 13 patients was chemically hypothyroid (thyroxine, 3.6 μg/100 ml; estimated free thyroxine, 0.8 ng/100 ml), although there were no clinical signs of hypothyroidism. Whether this finding was related to her unusually high plasma level (322 ng/ml) within the desipramine group is unknown. Desipramine plasma levels of the 7 patients who received benztropine mesylate, 1–2 mg/day, with the antipsychotic drug did not differ significantly from the plasma levels of the 8 patients receiving an antipsychotic without benztropine.

In order to assure that the difference in desipramine plasma levels observed in this sample was not the result of medication other than the antipsychotic agent, plasma levels of the 17 patients receiving no other medications were examined. The mean (±SD) steady-state plasma concentrations were 95±61 ng/ml for the 12 patients receiving desipramine alone and 274±154 ng/ml for the 5 patients receiving desipramine and an antipsychotic but no other drugs; the difference between these two samples was significant (Mann-Whitney, $p<.01$).

DISCUSSION

In our patient sample, the magnitude of the effect of antipsychotic drugs on desipramine plasma concentration is considerable. The fact that the plasma level was more than double in patients receiving antipsychotic drugs suggests that the magnitude of this effect may be of clinical importance. The relationship of plasma levels of desipramine and therapeutic response has not been well-defined; however, if analogous to nortriptyline this drug has a therapeutic window, which Friedel and associates (13) suggest may be between 40 and 160 ng/ml, then the effect of antipsychotic drugs on plasma concentration after usual doses of desipramine would be sufficient to raise the drug level beyond the therapeutic range. The elevated plasma concentration might also increase the incidence of toxicity. In our sample the 4 patients with serious side effects—urinary retention (N=1), a grand mal seizure (N=1), and a toxic brain syndrome (N=2)—had desipramine concentrations above 200 ng/ml. While the concurrent use of an antipsychotic drug in these patients may have also contributed to toxicity, each of the patients improved following reduction of the antidepressant drug without a change in the antipsychotic agent.

Although previous reports (3–8) suggest the metabolism of various tricyclic drugs may be impaired by different antipsychotic drugs, our data, as well as those of others (7, 8), suggest that desipramine may be particularly sensitive to this effect. The design of this study does not exclude the possibility that delusional patients may metabolize desipramine differently; however, the data of Gram and associates (3–6) indicate that inhibition of microsomal enzymes by neuroleptics is a more likely explanation. Although the clinical value of determining tricyclic concentrations has been debated, the use of combination antipsychotic-antidepressant drug therapy may be one indication for their measurement.

Brief Group Psychotherapy with Chronic Hemodialysis Patients

BY DAVID R. CAMPBELL, M.D., AND BIRENDRA K. SINHA, PH.D.

The authors selected 11 chronic hemodialysis patients for a brief group psychotherapy program, the primary objective of which was to produce cognitive and affective changes pertaining to the illness. Each of the 10 therapy sessions lasted 1 1/2 hours and was conducted while the patients were actually on dialysis. Three therapists rated outcome as "good," "fair," or "poor" on 10 objective criteria, and subjective impressions of the group experience were obtained from each patient. The study demonstrated the beneficial effects of group therapy, although there was no statistically significant difference between patients in the three outcome categories.

Several studies have suggested that hemodialysis patients experience a great deal of psychological stress manifested by a variety of behavioral symptoms (1–4). Specifically, hemodialysis patients are found to suffer from disturbances of body image (5–7), sexual fears including impotence (7, 8), and fear of death (9). Perhaps the most important observation has been the presence of suicidal tendencies and depression (3, 5, 8–11). Abram and associates (11) reported that the incidence of suicide among hemodialysis patients is greater than 400 times that of the general population. The patients who deteriorate and eventually die are those who demonstrate depressive symptoms, such as withdrawal, acting out behavior, or refusal to follow dietary restrictions. Depression and suicidal behaviors along with denial of illness require some form of psychotherapeutic intervention in order for the patients to cope with the problems of chronic illness (6, 10, 12, 13).

Although psychiatric treatment of hemodialysis patients has included both individual (14) and group (15–17) psychotherapy, group psychotherapy appears to be the preferred mode of treatment in many renal units of hospitals. Published reports indicate success with a variety of group psychotherapy methods that emphasize different dimensions of the therapy process. For example, Wijsenbeck (7) used group therapy while the patients were off dialysis, and the therapist's task was to "listen and observe." In a recent article, Buchanan (15) described a short-term, open-membership group

therapy program that involved both kidney transplant patients and their families. The therapy process focused on group cohesiveness, imitative behavior, development of socialization techniques, demonstration of family dynamics, ventilation, interpersonal learning, instillation of hope, altruism, information dispersal, and universality. Although the group therapy did not produce expected change in all 10 dimensions, Buchanan observed that the group was helpful in providing emotional support to the patients and the opportunity to learn adaptive strategies from others in the group.

The main purpose of our study was to ascertain the effectiveness of brief group psychotherapy with long-term hemodialysis patients. We used objective criteria for selecting patients and determining therapeutic outcome. A major innovative approach used by us was to conduct group sessions while the patients were actually on dialysis. The therapist and cotherapists were active participants in all group sessions and focused on specified aspects of the therapy process.

METHOD

Patient Selection

We selected 11 dialysis patients (8 men and 3 women) ranging in age from 20 to 50 years for group psychotherapy out of 18 patients referred for psychiatric consultation by the nephrologist in charge of the renal unit of the University of Alberta Hospital. Depression and management problems were the primary reasons for psychiatric referral. All patients had high T scores (> 80) on the Depression and Hypochondriasis scales of the MMPI.

The demographic characteristics of the patients are presented in table 1. The majority of the patients were under 25 years of age. The younger patients had a tendency to act out more and to present management difficulties. Although all 18 patients initially referred for psychiatric consultation had problems related to depression, somatic complaints, and hostility, the following criteria were used for selecting patients for the group therapy program.

1. *Severity of depression versus management problems.* The patients exhibiting difficult management problems such as acting-out behaviors or defiance and hostility toward the staff and treatment regimen were included in the program. Severely depressed patients were referred for more intensive individual therapy and chemotherapy.

2. *Acceptance versus denial reaction.* It appeared to us that acceptance of illness was related to severe depression, and we excluded such patients from the program. However, we considered depression combined with hostility and acting-out problems suitable for group therapy.

3. *Sexual concerns.* The patients with primary psychological problems related to sexual effectiveness were excluded from the study because we felt they could be best treated with individual psychotherapy.

4. *Indication of psychotic process.* The patients exhibiting clearly identifiable psychotic symptoms were considered unsuitable for group therapy.

5. *Length of time on dialysis.* In order to introduce patients to group processes at an early stage of the disease, we excluded those who had been on dialysis for more than 6 months from this study.

TABLE 1
Demographic Characteristics of 11 Dialysis Patients Selected for Brief Group Psychotherapy

Characteristic	Number	Percent
Age (years)		
20–24	5	45.4
30–34	2	18.2
35–39	1	9.1
45–49	2	18.2
50–55	1	9.1
Marital status		
Single	5	45.4
Married	6	54.6
Employment status		
Employed	2	18.2
Student	3	27.3
Housewife	3	27.3
Unemployed	3	27.3
Socioeconomic status		
Middle class	9	81.8
Working class	2	18.2

Group Process

Two groups consisting of 6 and 5 patients each were formed. The brief group therapy sessions took place every other week and lasted 1½ hours. There were a total of 10 sessions.

The primary objective of the group therapy was to produce cognitive and affective changes pertaining to the illness. Specifically, cognitive changes were concerned with the patient's perception and explanation of illness. As suggested by Pritchard (18), a physically disabled person is likely to perceive his illness "as an enemy which is attacking him" (p. 55). Such a perception may, in turn, cause undesirable affective responses, such as hostility, anger, anxiety, and feelings of helplessness. Hence, the group psychotherapy aimed at changing the patient's perception so that illness could be viewed as a challenge rather than an enemy. We expected that the new perception of kidney failure as a problem-solving task would produce positive emotional responses in the patients.

The group sessions were conducted by a therapy team consisting of one psychiatrist and two nurses, one from the renal unit and the other from the hospital's psychiatry ward. The psychiatrist was the therapy leader, and the two nurses served as cotherapists. The group process focused on active verbalization and expression of feelings. As an active member of the

group, the group leader took a confronting attitude. Rational examination of feelings and cognitive restructuring were attempted with respect to specified psychological difficulties of the group members. At times, the therapist provoked the patients with direct interpretation of the initial complaints. Personal and social consequences of low motivation, hostility, and depressed attitudes with respect to the dialysis management routine were discussed in all sessions. While the therapist was active and direct, the cotherapists were supportive. Their supportive role appeared necessary for the depressed patients to express themselves and contribute to the group sessions.

The therapists did not attempt depth analysis of the patient's underlying motivations. In fact, healthy defenses, such as rationalization, suppression, or substitution, were reinforced. However, the group process provided some insight into unhealthy defenses, such as denial, displacement, and projection, that were frequently employed by the patients during initial therapy sessions.

Evaluation Criteria

We evaluated the effectiveness of the group therapy program after 10 sessions in terms of clinical judgment of the therapy team obtained through their ratings on 10 relevant criteria and the patients' evaluation of their group experience. We selected the following relatively objective criteria for evaluating the program because of their clinical importance in the management of dialysis patients: 1) control of diet and fluid control; 2) improved interpersonal communication with staff, patients, relatives, and friends; 3) return to work, including part-time employment and/or a suitable educational program; 4) acceptance of the kidney unit; 5) decreased fear of actually running on the machine; 6) reduced depression and/or demanding and acting-out behavior; 7) decreased somatic complaints, such as nausea, vomiting, headache, pain, during dialysis or ward activities; 8) ability to cope with minor (e.g., vein clot) and major stress (e.g., death of a patient on dialysis in the next bed); 9) changes in the patient's attitudes and feelings toward staff, relatives, and friends; and 10) changes in the attitudes and feelings of the staff, relatives, and friends toward the patient.

Each patient was rated "good," "fair," or "poor" by the psychiatrist and the two nurses independently. The three raters provided a total of 30 ratings for each patient. The most frequently rated category was used as the final score; e.g., if a patient received 15 good, 8 fair, and 7 poor ratings, he was placed in the good category. In case of equal distribution of the three categories the psychiatrist made the final judgment about the therapy outcome. Thus, the therapy outcome was based upon a composite evaluation by pooling the observations of the therapy team. Although the therapists rated the patients independently, the ratings cannot be considered truly independent because the raters worked together in group sessions. Hence, no attempt was made to establish interrater reliability.

We obtained the patients' evaluation of the group therapy program in the form of written comments about their overall subjective impressions. No attempt was made to quantify the patients' evaluations.

RESULTS

The initial group sessions revealed that denial of illness and fear of death were the primary areas of concern. Reference to poor kidney function and its fatal consequences was avoided in group discussions. When there was a death on the renal unit, the group therapy patients had a tendency to ascribe the cause to heart or lung failure rather than the kidney problem. As the group progressed, the members became increasingly supportive of each other. They became more objective in dealing with stressful situations, such as death of a dialysis patient.

Depression and apathy were other areas of major concern in the therapy sessions. However, increased verbalization, open communication, and close interaction between members were clearly noticeable during later group sessions. The patients showed greater concern for the welfare of other members and exchanged advice for better management of their kidney problem. The group therapy sessions seemed to promote the feeling of self-worth and hope in the future. Even sexual matters were discussed in a lighter vein in the form of jokes.

We felt that the degree of mutual trust and group cohesiveness among dialysis patients was much lower than that achieved by other successful therapy groups. The lack of trust was mostly with reference to doctors, nurses, and family members. These physically healthy persons were, perhaps, constant reminders to the patients about their dependence on others. During the period of our study, several dialysis patients had died in the unit. Death of fellow patients might have reactivated the group members' fear of death and dampened their faith in the effectiveness of the dialysis machine. The same psychological processes might account for the slow development of group cohesiveness. It was difficult to achieve open communication and close interpersonal relationships between group members when denial of illness was one of the frequently used defense mechanisms. However, as the group progressed, the patients tended to accept their handicap as well as the fact that their survival was contingent upon regular use of the dialysis machine.

Approximately 64% (N=7) of the patients were rated good, 18% (N=2) were rated fair, and 18% (N=2) were rated poor. A chi-square test did not reveal significant difference between the three outcome categories. However, when the combined good and fair categories are compared with the poor category,

the difference approaches statistical significance ($p<.10$). The lack of a statistically significant difference is probably due to our small number of cases.

All patients indicated in their written comments that they benefited from the group experience with respect to depression, acceptance of the illness, body image, and self-esteem. Even those who were judged poor by the therapy team had positive feelings about the group therapy program. In general, the patients became more cooperative in following the strict regimen imposed by the dialysis treatment program.

CONCLUSIONS

This study demonstrates the value of group therapy without taking the patients off the dialysis machine, providing a situation of direct confrontation since the machine is an immediate reminder to the patients that they have a serious physical disability. Our criteria for selecting the patients and evaluating the therapy outcome appear valid and promising; however, in view of a statistically insignificant difference in the therapy outcome as rated by the treatment team, further research is needed to identify the variables most sensitive to therapeutic intervention. Our study also does not compare the effectiveness of individual and group therapy. Such a controlled comparison on quantifiable dimensions would certainly help the consulting psychiatrist in planning therapeutic programs suitable for individual patients.

Credibility and Incredibility: The Psychiatric Examination of the Complaining Witness

BY ROBERT LLOYD GOLDSTEIN, M.D.

Psychiatrists are called on to evaluate the credibility (and incredibility) of complaining witnesses in criminal proceedings despite a longstanding controversy about their ability to accurately make such determinations. The author discusses the history of such psychiatric activity from Freud through the Alger Hiss perjury trial, its current status in terms of benefits to the criminal justice system, the legal and social questions it raises (e.g., the competing issue of the complainant's right to privacy), and the court's restrictions on the psychiatrists. He presents two illustrative case histories.

In 1906, in one of his rare ventures into the area of forensic psychiatry, Sigmund Freud delivered a lecture before a University of Vienna law class titled "Psycho-Analysis and the Ascertaining of Truth in Courts of Law" (1). He suggested that the psychiatrist may have at his disposal scientific means by which the testimony of witnesses can be tested for truthfulness and reliability but cautioned that these scientific methods were of a highly experimental nature and for research purposes only. They were not intended to influence the verdict of the court.[1] He thus anticipated a controversy that has raged on for three quarters of a century regarding the psychiatrist's special ability to evaluate the credibility of the complaining witness in a legal proceeding.

Davidson (2) contended that the psychiatric appraisal of the witness represents a new field of forensic psychiatry. He described nine clinical conditions that the psychiatrist alone is qualified to discern and to relate to the credibility issue: 1) schizophrenia, 2) senile psychoses, 3) manic states, 4) paranoid states, 5) drug addiction, 6) mental deficiency, 7) alcoholism, 8) psychoneurosis, and 9) psychopathic personality. Davidson (3) also stated, "If the psychiatrist were given all the facts about the witness' background; if he were given time to do a thorough physical and mental examination; if he could take a psychiatric history on the witness, he could give the trial lawyer a solid opinon about testimonial capacity."

The best known use of psychiatric evaluation of a complaining witness' credibility came in the second Alger Hiss perjury trial in 1949. According to Slovenko (4), the judged ruled,

> It is apparent that the outcome of this trial is dependent, to a great extent, upon the testimony of one man—Whittaker Chambers. Mr. Chambers' credibility is one of the major issues upon which the jury must pass. The opinion of the jury—formed upon their evaluation of all the evidence laid before them—is the decisive authority on this question, as on all questions of fact. The existence of insanity or mental derangement is admissible for the purpose of discrediting a witness. (4, p. 45)

The judge allowed a psychiatrist, Dr. Carl A.L. Binger, to testify that, in his expert opinion, Chambers was a "psychopath with a tendency toward making false accusations" (4, p. 45). This expert opinion was based on Binger's personal observation of Chambers on the witness stand and on a reading of some of Chambers' poems, plays, and book reviews. No psychiatric examination per se was carried out. The jury chose to disregard the psychiatric testimony and found Hiss guilty as charged.

In some jurisdictions, when the credibility of the complaining witness in sex offense cases is in doubt a psychiatric examination is ordered "not to determine whether the witness is telling the truth, but to determine whether the emotional or mental condition of the witness *may* affect his or her ability to tell the truth" (5). A report of the American Bar Association (6) recommended psychiatric examination of all complainant women in sex offense cases to ascertain the presence of a psychiatric disturbance. Proponents of psychiatric involvement believe that psychiatry has firmly established itself as an inextricable cog in the machinery of the law and that it would be better if the system availed itself of psychiatric expertise when the alternative

[1] In a memorandum prepared in 1922 that is not extant, Freud deprecated any half-baked application of psychoanalytic theories in legal proceedings.

might be to rely on uniformed ignorance, myths, and misconceptions (7, 8).

Critics of psychiatric involvement have raised serious questions in regard to the desirability, accuracy, and effectiveness of psychiatric evaluations of credibility. In 1909 Wigmore (9) asked, "Where are the exact and precise experimental and psychological methods of ascertaining and measuring the testimonial certitude of witnesses?" According to Slovenko (4), the judge in a famous rape case ruled that the jury alone would best decide the issue of the complaining witness' credibility. The judge refused to allow the introduction of psychiatric testimony:

> We are not convinced that the time-honored and well settled and undefined rule of impeachment of the veracity of a witness should thus be innovated upon. It is yet to be demonstrated that psychological and medical tests are practical and will detect a lie on the witness stand. (4, p. 49)

Other courts have been even more skeptical:

> The divergence of psychiatric opinion and its frequent inexactness render its value minimal in enabling the jury to decide the issue of credibility . . . the jury after being subjected to several conflicting, equivocating and highly technical psychiatric opinions may actually be more confused than before. (4, p. 59)

Another court failed to see the benefit to be gained from "an amateur's voyage on the fog-enshrouded sea of psychiatry" (4, p. 59).

There is a great deal of concern about reducing the prerogatives of the jury and giving a psychiatric expert the power to decide the issue of credibility (10), about the competing interests of witness credibility and privacy, and about the possible misuse of psychiatry by calling for psychiatric opinions based on questionable practices that are not firmly grounded in good clinical evaluation methods. Slovenko (4) concluded,

> To obtain an ideal climate for an effective psychiatric evaluation, a number of legal reforms would be necessary that might be unwise either from a social or legal point of view. If this is the case, then psychiatrists and jurists should realize the limitations that the legal procedure places on the accuracy and effectiveness of the psychiatric examination and, in turn, on the psychiatric opinion. (p. 56)

Following are case reports in which the court permitted testimony by a psychiatrist (myself) as to the mental state of the complaining witness. In these cases it was the contention of the defense that the mental disorder of the complaining witness and not reality was the source of the complaint. A direct psychiatric examination of the complainant, an approach that was promoted as being more accurate and rewarding, was requested in both cases. The court denied permission but did allow psychiatric testimony based on a review of the complainant's psychiatric hospitalization records. This might be viewed as a compromise between the competing issues of a need to evaluate credibility and a desire to infringe on the privacy of the complainant as little as possible.

CASE REPORTS

Case 1. A 74-year-old woman who lived alone claimed that the son of her building superintendent had assaulted and robbed her. He was arrested the same day. He had known the complaining witness for more than 10 years and lived in the same building. He emphatically denied the charges against him but had no solid alibi. He was unemployed and had a criminal record and a history of drug abuse (he was currently attending a methadone program). Shortly before the trial it came to light that the complainant had had several psychiatric hospitalizations since age 45 for paranoid schizophrenia, characterized by delusions, hallucinations, confusion, memory lapses, and antagonistic behavior toward friends and family. During these episodes she had delusional ideas of being robbed of cherished possessions. She even accused her relatives of stealing from her. As a result of these disclosures, the court ruled that a psychiatrist retained by the defense could review her psychiatric records and testify as to the possible influence of her mental condition on her credibility. I testified that in view of her documented psychiatric history and the particular nature of her disorder, there was a substantial index of suspicion that her testimony represented another example of delusional thinking. I conceded that my opinion would be more cogent if it were based on a direct psychiatric examination of the woman. The jury acquitted the defendant. It appeared that the impact of psychiatric testimony was facilitated by the overall weakness of the prosecution's case, which was based on the complainant's word without any other corroboration.

Case 2. A 40-year-old woman charged that her boyfriend had raped her. She stated that he had visited her to inform her that their liaison could not continue because his estranged wife was returning to live with him. She alleged that he forcibly raped her after they quarreled. She made no outcry about this until 3 days later. During a gynecological examination 2 days after the alleged rape, she made no mention of a sexual assault. It was learned that she had been hospitalized twice in recent years for depressive illness with hysterical features. One month before the alleged rape she underwent a hysterectomy. The court allowed me as defense psychiatrist to review her hospital records but not to examine her directly; the court stated that a direct psychiatric examination was an unacceptable invasion of her privacy. I testified as to the possible effects of narcissistic blows to the complainant as a result of her hysterectomy and being abandoned by her boyfriend. I talked about possible relationships between narcissistic injuries of this nature, a personality makeup including depressive and hysterical traits, attempting to maintain a shaken feminine self-image, and allegations of rape at length before the jury. The jury could not find the defendant guilty of rape "beyond a reasonable doubt," and he was acquitted.

DISCUSSION

A psychiatric evaluation of the complaining witness in a criminal proceeding may be necessary to allow for informed deliberation by the jury. In cases where doubt exists as to whether the complainant may be psychiatrically impaired, information regarding the mental state of the complainant is germane and should be made fully clear to the jury if the jury is to function meaningfully. The determination of the effect of any psychiatric condition on the credibility of the complaining witness remains the sole province of the jury; nonetheless, information provided by an expert witness permits the jury to make informed decision as to that witness' worth.

To enhance the truth-finding function of the jury, courts have ruled that they have an inherent power to order the complainant to cooperate. Not only is such testimony admissible, but the Court of Appeals in New York State has reversed convictions in which such information was not put before the jury (11, 12). The court held that the inability of the jury to appreciate the nature of the psychiatric infirmity was sufficient grounds to overturn the conviction. The purpose underlying the testimony of an expert is not to substitute his or her estimation of credibility for that of the jury. Rather, it is to provide a scientific perspective for the jury according to which it can then evaluate the complainant's testimony for itself.

Scrutiny of the psychiatric condition of the complaining witness is an area of forensic psychiatry that warrants continuing study. Is the psychiatrist invading the usual province of the jury? Is he or she really determining the credibility of the complaining witness or being used to discredit the complainant improperly? Slovenko asked, "Is psychiatry here being used more for its prestige value than for its probative value?" (4, p. 56). Is the privacy of the complainant being invaded to an unacceptable extent? A New York State court has ruled that although the right to psychiatric testimony clearly exists, the defendant must make a clear showing that it is warranted in view of the infringement on the complainant's right to privacy (13). Is it the complainant who will be tried instead of the defendant? Will this serve to discourage victims of crime from pressing charges for fear they may be exposing themselves to humiliation and vilification? Proponents of this trend have already tried to expand it further: it has been argued that the presentation of critical scientific data as to the psychiatric condition of a complainant should not depend on the chance that he or she has a history of psychiatric illness warranting closer scrutiny. Where there is no history, some have contended that there is an a priori right to launch such an inquiry before trial. This would certainly place on trial all complaining witnesses, whether or not they have a psychiatric history.

I have suggested the term "incredibility" to describe that quality in a witness which renders his or her evidence unworthy of belief. Although the invention of a technical term may help to clarify an issue and avoid confusion and distortion, it can also give the appearance of creating facts for the social sciences (14). Psychiatry already has plenty of such facts in the form of technical terms, and these are reified and often misused in the courtroom and other places to overawe those who are not used to scrutinizing authorities. The danger is that determinations of incredibility, if not managed judiciously and vigilantly, might be overused and misused to harass and stigmatize complaining witnesses. It remains to be seen what impact this direction in psychiatry's involvement in court proceedings will have, what specific guidelines and safeguards will evolve for its application, and what will result from renewed conflicts between the individual's right to privacy and the jury's right to know in order to ensure a fair trail and to protect the accused. This is but a further example of the constant need to adjust two conflicting ideals in the law so that one is not sacrificed to the other. Just as Freud cautioned against "wild analysis" as a reckless and blind misuse of psychoanalysis, so must the forensic psychiatrist avoid introducing any testimony based on incomplete, inadequate, or questionable methods of clinical evaluation in order to aid the legal process in reaching more informed and intelligent decisions.

Plasma and Saliva Levels of Chlorpromazine and Subjective Response

BY THEODORE VAN PUTTEN, M.D., PHILIP R.A. MAY, M.D., DONALD J. JENDEN, M.D., ARTHUR K. CHO, PH.D., AND CORALEE YALE, M.A.

Newly admitted schizophrenic patients (N=48) were given a test dose of 2.2 mg/kg of chlorpromazine hydrochloride by mouth. Chlorpromazine was measured in plasma and saliva at 1, 2, 3 (saliva only), 4, 6, 8, 12 (saliva only), and 24 hours by gas chromatography-mass spectography. Subjective response at 4 and 24 hours after test dose was not significantly related to either plasma or saliva level even for dysphoric responders. Dysphoric responses to chlorpromazine appear to be idiosyncratic—rooted perhaps in altered receptor sensitivity or in a patient's very personal interpretation of drug effect.

The subjective response to the first dose of antipsychotic medication is important. If the patient finds the medication agreeable or helpful (a syntonic response), all is well. A dysphoric response, however, augurs poorly. In our experience an initial dysphoric response is a powerful predictor of drug noncompliance, no matter how hard the therapist tries to correct it or how understanding he tries to be (1, 2). Even if the patient can be persuaded to continue the medication, an early dysphoric response is modestly predictive of an inferior short-term outcome, at least at conventional dosage levels (1).

The dysphoric responders in the present study experienced the drug effect as unbearable. From the very beginning they reported that chlorpromazine made them "goofy," "lazy," "mummified," "dull," or "fuzzy." All experienced the medication as "too strong" and requested, in fact demanded, that the dosage be reduced.

Since there is enormous variability in blood levels after a single dose of chlorpromazine (3, 4), we hypothesized that dysphoric responders would have deviant pharmacokinetics—in particular, higher blood levels.

METHOD

The subjects were 48 schizophrenic patients newly admitted (or readmitted) to Brentwood Veterans Administration Medical Center who had given informed consent and for whom treatment with an antipsychotic drug was considered appropriate. They were suffering from a functional psychosis, schizophrenic type, but not from organic brain disease, significant physical disease, or major drug addiction or alcoholism.

In general, the patients were admitted voluntarily (79%). Most were in young middle age (mean age±SD=32.3±9.9 years), had never been married (79%), and had a chronic disorder (mean duration=6.4±6.93 years) and a fair prognosis. On a nursing observation scale (NOSIE) (5), their mean overall degree of severity of illness was 4.72 (4=moderately ill and 5=markedly ill).

The patients were rated on four different sets of diagnostic criteria for schizophrenia: the NIMH schizophrenia criteria (6), the New Haven Schizophrenia Checklist (7), the Diagnostic Rating Scale (8), and the World Health Organization criteria (9). For 40 of the 48 patients all 4 diagnostic criteria confirmed a diagnosis of schizophrenia; for 6 patients 3 of the 4 criteria confirmed this diagnosis. Of the remaining 2 patients, 1 was rated as "probably" schizophrenic, and the other as having schizoaffective psychosis. A 2- to 7-day washout period was provided; most patients, however, had not taken medication for several months and could be presumed to be drug-free on admission.

An initial test dose of 2.20 mg/kg of chlorpromazine hydrochloride was given to each patient as oral concentrate. They were given a light standardized meal 2-

This project was supported by the Medical Research Service of the Veterans Administration. Computing assistance was provided by the Computing Facility at the Center for the Health Sciences, University of California at Los Angeles, which is sponsored by National Institutes of Health grant RR-3.

Jane A. Kirksey assisted in data processing, and the manuscript was typed by Rosa Surrence. Lorraine A. Wittman obtained the blood and saliva specimens and did the preliminary processing; Emma Di Stefano did the gas chromatography-mass spectography analyses; Wilfred J. Dixon, Ph.D., gave statistical advice; and A. Maniau, Ph.D., provided $^{2}H_{6}$-chlorpromazine.

3 hours after the test dose. Blood and saliva samples were taken at 0, 1, 2, 3 (saliva only), 4, 6, 8, 12 (saliva only), and 24 hours. Chlorpromazine was measured in plasma and saliva by gas chromatography-mass spectography with *N, N*-bisperideuteromethyl chlorpromazine ($^2H_6$-chlorpromazine) as an internal standard. A dental cotton roll was used to collect the saliva specimens in order to avoid a psychologically distasteful instruction to "spit." Details of the collection and assay methods are given elsewhere (3).

Subjective response was assessed by a semistructured interview in which the following questions were asked: "How does the medication agree with you?" "Does it make you feel calmer?" "Does it affect your thinking?" and "Do you think this would be the right medicine for you?" The subjective response was graded on a syntonic-dysphoric continuum on a scale from +44 (maximum syntonic response) through −44 (maximum dysphoric response), as reported previously (1).

Subjective response was measured at 4 and 24 hours after the test dose. Patients were divided according to their scores into "syntonic," "indifferent," and "dysphoric" responders: greater than 5=syntonic responder, +5 through −5=indifferent responder, less than −5=dysphoric responder.

RESULTS

Plots of the logs of plasma and saliva chlorpromazine against time for the dysphoric (N=10), indifferent (N=4), and syntonic responders (N=18) did not reveal any obvious relationship between subjective response and either blood or saliva level.[1] The dysphoric responders did not have higher blood or saliva levels than syntonic or indifferent responders; the shape of the curve for all three groups was similar. Pearsonian correlations of subjective response at 4 and 24 hours with the respective plasma and saliva levels (whether raw or logarithmic) were not statistically significant.

Different cutting points for dysphoric, syntonic, and indifferent responders still did not yield significant differences. Further, even the most extreme dysphoric responders were not different in their plasma and saliva levels: for example, the patient with the highest plasma and saliva levels was semicomatose at the time of the peak levels; at 24 hours, his plasma level had fallen to 137 pmol/ml, at which time he was only mildly dysphoric. (He went on to have a good objective and subjective outcome on a very low dose of chlorpromazine).

Subjective response to a test dose of chlorpromazine ranged widely, from +36 through −36 (mean score±SD=4.8±16.6) at 4 hours and from +33 through −44 (mean score=4.9±16.9) at 24 hours. There were no relationships between subjective response and age, duration of psychotic symptoms, diagnosis (paranoid versus nonparanoid schizophrenia), peak drowsiness ratings (subjective or objective), or initial clinical state (1).

COMMENT

Whatever the reason for dysphoric responses to chlorpromazine, our data indicate that pharmacokinetics is not the answer. When the dysphoric responder tells us that the medication is too strong or that we are "poisoning" him, the explanation is not an aberrant plasma chlorpromazine level. Dysphoric responses to chlorpromazine appear to be idiosyncratic, rooted perhaps in altered receptor sensitivity or a patient's very personal interpretation of drug effect.

[1]A figure showing subjective response versus blood and saliva levels is available from Dr. Van Putten on request.

Priorities in Psychiatric Residency Training

BY CHARLES L. BOWDEN, M.D., FREDERICK J. HUMPHREY, D.O., AND MICHAEL G.G. THOMPSON, M.D.

The authors surveyed 22 psychiatric educators to determine their views of the basic knowledge and skills that should be required for all psychiatric residents. A comprehensive document of educational objectives facilitated practical differentiation of responses. Diagnostic, problem-solving, and treatment-dispositional skills were particularly highly ranked. Such data may be useful in defining the profession of psychiatry as well as in curriculum planning.

The core curriculum for residency training is one of the critical issues now facing psychiatry. As Beigel (1) stated, this curriculum "must define concepts and areas of knowledge that all psychiatrists should possess regardless of the specific application(s) which they later choose for this knowledge and be subject to evaluation according to defined criteria." Benefits may result from consensually derived curriculum objectives, especially if these are ranked as to importance. Psychiatric educators and residents would have objective information on which to base curriculum planning and clinical experiences. Accountability might be improved. With general agreement about the content of psychiatric residency education, individual programs should be better able to establish expected levels of proficiency and to develop evaluation methods to document that proficiency. The curriculum task force of the American Association of Directors of Psychiatric Residency Training surveyed psychiatric educators to determine their views about the degree to which a broad range of objectives is essential in residency training. The results are reported in this paper.

The objectives used for the survey are those developed by the Canadian Coordinators of Psychiatric Education, a listing of more than 900 objectives in 19 topic areas describing knowledge and clinical skills relevant to psychiatric education (2). One advantage of such detailed objectives for this survey was that important differences in emphasis within a subject area might become evident. For example, skills in psychopharmacology almost certainly would be ranked high by all psychiatrists. However, by subdividing the area of psychopharmacology into enabling objectives, such as "ability to state . . . the general chemical formulae for the class of drug" and "ability to state theoretical sites of action in the brain," objectives that most respondents considered less important, we can begin to establish limits for the core levels of knowledge and skills to be attained in various subject areas during residency training.

METHOD

The questionnaire, which took 4 to 10 hours to complete, was distributed to 36 psychiatrists, 22 of whom responded: 15 were psychiatric residency directors, 3 were undergraduate psychiatric education directors, 2 were members of the American Board of Psychiatry and Neurology, and 2 were chief residents. Twenty respondents were affiliated with medical-school-based training programs, and 2 were directors of state hospital programs. Four were from the northeast, 5 from the southeast, 8 from the midwest, 3 from the southwest, and 2 from the west.

For each objective the respondent indicated whether it should be considered essential for all residents, moderately emphasized, or touched upon/optional.

RESULTS

Table 1 lists those objectives considered essential by at least 50% of the respondents. Table 2 lists illustrative examples of objectives ranked as essential by less than 50% of the respondents. A complete list of the rankings for all 900 objectives is available from the first author.

TABLE 1
Residency Training Objectives Ranked Essential by at Least 50% of 22 Psychiatric Educators

Objective	Essential		Moderate Emphasis		Touched Upon/ Optional	
	Number	Percent	Number	Percent	Number	Percent
Knowledge of major trends in contemporary psychiatry	14	63.6	7	31.8	1	4.5
Ability to assess normality and deviance from normality	18	81.8	2	9.1	2	9.1
Knowledge of effect of illnesses and medications on sexual behavior	14	63.6	7	31.8	1	4.5
Ability to compare male and female life cycles regarding achievement, motivation, affiliation, and sexuality	18	81.8	4	18.2	0	
Knowledge of function of limbic system	19	86.4	3	13.6	0	
Knowledge of function of hypothalamus, pituitary, and adrenal cortex	15	68.2	7	31.8	0	
Knowledge of function of lobes of cerebral cortex	13	59.1	8	36.4	1	4.5
Knowledge of relevance of neuroendocrine function to psychiatric disorders	14	63.6	6	27.3	2	9.1
Knowledge of biological concomitants of stress reaction	14	63.6	6	27.3	2	9.1
Knowledge of biochemical theories of schizophrenia and affective disorders	20	90.9	2	9.1	0	
Knowledge of distribution and metabolism of neurotransmitters	16	72.7	5	22.7	1	4.5
Knowledge of genetic transmission of psychiatric disorders	13	59.1	8	36.4	1	4.5
Knowledge of indications for CT scan, lumbar puncture, etc.	15	68.2	7	31.8	0	
Knowledge of indications for biofeedback	13	59.1	7	31.8	2	9.1
Knowledge of effect of brain syndromes on intelligence	11	50.0	9	40.9	2	9.1
Ability to clinically distinguish schizophrenic language difficulties	14	63.6	2	9.1	6	27.3
Knowledge of relationship of psychiatric disorders to social class	13	59.1	8	36.4	1	4.5
Knowledge of developmental milestones of children	13	59.1	8	36.4	1	4.5
Knowledge of indications for common child psychiatric treatment techniques	15	68.2	4	18.2	3	13.6
Knowledge of developmental tasks of adolescence	21	95.5	1	4.5	0	
Knowledge of indications for adolescent psychiatric treatment	19	86.4	2	9.1	1	4.5
Ability to differentially diagnose mental retardation	16	72.7	4	18.2	2	9.1
Knowledge of genetic basis of psychiatric disorders	15	68.2	7	31.8	0	
Knowledge of family's role in patient's condition	17	77.3	4	18.2	1	4.5
Ability to present a comprehensive case history of all major diagnostic groups	20	90.9	1	4.5	1	4.5
Knowledge of basic psychoanalytic concepts	21	95.5	1	4.5	0	
Ability to outline the mental mechanisms commonly used in neuroses and psychoses	21	95.5	1	4.5	0	
Skill in psychiatric consultation	21	95.5	0		1	4.5
Ability to competently interview (including mental status exam), differentially diagnose, and establish treatment plan for all *DSM-III* disorders	22	100.0	0		0	
Ability to conduct complete physical exam	20	90.9	2	9.1	0	
Ability to use laboratory tests in diagnosis	19	86.4	3	13.6	0	
Ability to determine characterological coping patterns in patient under stress	21	95.5	1	4.5	0	
Ability to assess patient's resources, problem-solving ability, and flexibility of defenses	21	95.5	1	4.5	0	
Knowledge of main characteristics of crisis reactions	16	72.7	4	18.2	2	9.1
Ability to assess and manage psychiatric emergencies	22	100.0	0		0	
Knowledge of basic epidemiologic data on suicide	16	72.7	6	27.3	0	
Ability to assess and treat grief reactions	21	95.5	1	4.5	0	
Knowledge of biological correlates of psychophysiologic disorders	15	68.2	6	27.3	1	4.5
Knowledge of role of life stress and learning theory in psychophysiologic disorders	15	68.2	6	27.3	1	4.5
Ability to assess and treat psychophysiologic disorders	21	95.5	0		1	4.5
Ability to assess and treat psychosocial complications of physical illness	20	90.9	2	9.1	0	
Knowledge of psychological theories of neuroses	15	68.2	7	31.8	0	
Skill in treating neuroses	21	95.5	1	4.5	0	
Ability to describe drug treatment for personality disorders	20	90.9	2	9.1	0	
Ability to describe group treatment for personality disorders	19	86.4	3	13.6	0	
Ability to describe behavior therapy for personality disorders	16	72.7	6	27.3	0	
Knowledge of treatment for alcohol and drug abstinence syndromes	19	86.4	1	4.5	2	9.1
Knowledge of treatment approaches for sexual deviations	16	72.7	4	18.2	2	9.1
Knowledge of etiological hypotheses for functional psychoses	22	100.0	0		0	
Ability to treat functional psychoses	20	90.9	1	4.5	1	4.5

Experience in community consultation	9	40.9	7	31.8	6	27.3
Clinical experience in a geriatric setting	8	36.4	4	18.2	10	45.5

DISCUSSION

Highest emphasis was given to practical clinical objectives, such as being able to describe the clinical manifestations and clinical course, evaluation, differential diagnosis, and treatment of the major psychiatric disorders. Objectives focusing on the vicissitudes of normal development and phase-specific conflicts,

especially those during childhood, adolescence, and old age, were also given high rankings. In terms of treatment skills, emphasis was placed on individual psychotherapy and psychopharmacology. From a theoretical standpoint, psychodynamic objectives were given greater emphasis than learning theory and behavioral modification objectives. The latter, however, were emphasized more than less commonly used approaches, such as Gestalt and rational-emotive therapies. Child and adolescent psychiatry objectives were consistently ranked lower than similar adult objectives. This held true for skill objectives, such as differential diagnosis and treatment, as well as theoretical constructs. It suggests that the emphasis in basic training is considerably more on adult psychiatry than on general psychiatry. Much of the detailed information from biological, psychological, and sociological sciences was not considered to be essential. Several respondents indicated that many of these objectives were more suitable as precursory experiences.

Regardless of the content area, certain kinds of objectives were generally considered outside the essential experience of the resident. These included listing the contributions of famous people, detailed knowledge of less common treatment techniques, levels of mastery suitable for a psychiatric subspecialist, and mastery of theoretical information, especially if not objectively established.

The current study indicates those objectives which psychiatric educators consider essential. The respondents were a select group in several ways. The majority were directors of psychiatric residency training who were sufficiently motivated to devote several hours to the survey. Their knowledge and concern about curricular matters was probably above average. One might expect such a group to have unusually broad definitions of the scope of training. Their parsimonious view of what constitutes essential knowledge and skills is therefore noteworthy.

The small number of psychiatrists surveyed clearly marks this as a pilot study that would benefit from some form of replication with a larger and more diverse group of psychiatrists or psychiatric residents. The American Association of Directors of Psychiatric Residency Training is surveying residents completing training to determine how well their programs met these core objectives.

The data presented here can facilitate establishing a core curriculum in content and experiences. The rankings should aid in identifying discrepancies between what psychiatric educators consider important and the experiences actually provided residents. The data may also be useful in professional boundary sharpening—defining those things for which psychiatrists are uniquely qualified, areas of overlap with other medical specialties and mental health practitioners, and areas largely outside or peripheral to the basic competencies of psychiatrists.

Should Psychic Studies Be Included in Psychiatric Education? An Opinion Survey

BY STANLEY R. DEAN, M.D., C.O. PLYLER, JR., M.D., AND MICHAEL L. DEAN. PH.D.

The authors received 228 responses to a questionnaire on psychic phenomena mailed to professors and residents in psychiatry, other medical faculty, and deans of medical schools. Fifty-eight percent of the respondents believed that an understanding of psychic phenomena is important to future graduates of psychiatry, and 44% believed that psychic factors are important in the healing process. The authors believe that including psychic studies in psychiatric education would attract more medical students to psychiatry.

Meta psychiatry refers to the confluence of psychiatry and psychic phenomena. In addition to and including parapsychology, which deals primarily with ESP, telepathy, precognition, psychokinesis, reincarnation, and related fields, metapsychiatry includes many other paranormal manifestations that affect human behavior, e.g., altered states of consciousness, meditation and trance, out-of-body experiences, nonpsychotic hallucinations, postmortem survival, mind manipulation, charisma, voodooism, placebo effects, energy fields, and "Kirlian photography," cults, faith and the power of suggestion, voluntary control of autonomic functions (as originally practiced by esoteric sects and now confirmed by biofeedback techniques), and, above all, the scientific modus operandi of so-called miraculous healing. Already pointing in that direction are recent discoveries that endogenous histochemical mechanisms involving neurotransmitters, mood regulators, analgesics, and other reparative agents play an important role in the healing process, thus raising the strong possibility that exceptional emotional responses such as those associated with faith, suggestion, prayer, and placebo effects may greatly accelerate the speed and concentration of natural reparative biochemicals in somewhat the same manner as the well-known adrenal fight or flight mechanism.

Our own experience (1-3) and various surveys by others (4) have revealed an unprecedented degree of contemporary interest in psychic research among physicians and the general public. In his Presidential Address at the 1979 annual meeting of the American Psychiatric Association, Dr. Jules Masserman stated, "As to the third human proclivity for the arcane and occult, there is also a growing interest among us in what we call metapsychiatry" (5, p. 1015).

Unfortunately, little or no top level academic training in psychic studies has been available thus far; therefore, most educators are not aware of the added rich dimension such studies may provide in the therapeutic process. The purpose of this survey was to obtain an interprofessional consensus on the desirability of including psychic subjects in psychiatric and ancillary medical education. Our survey team consisted of a psychiatrist (S.R.D.), a specialist in family practice (C.O.P.) who was a former member of the Anglo-American Conference on Continuing Medical Education, and a marketing analyst (M.L.D.), who analyzed our computer-processed results.

METHOD

We used a national mail survey questionnaire to gather data because it was the most practical way to reach a broad-based, difficult-to-reach sample, was well suited to extensive rating scales, and assured anonymity to the respondents—a salient point in dealing with innovative subject matter (6). The questions were close-ended, with open-ended write-in options available for personal comments (7). Questionnaire completion time was minimized through the use of simple-to-record check-mark answers.

Questionnaires were mailed to 1,150 individuals: 293 deans of medical schools, 109 heads of departments of psychiatry, 261 professors of psychiatry, 419 residents in psychiatry, and 68 other medical faculty. Medical school deans and faculty members were mailed questionnaires directly. Psychiatric residents received

Revised version of a panel presentation at the 132nd annual meeting of the American Psychiatric Association, Chicago, Ill., May 12-18, 1979. Received May 8, 1979; revised Nov. 5, 1979, and Feb. 20, 1980; accepted April 4, 1980.

them for the most part through secondary redistribution by heads of departments. That procedure for residents was necessitated by their relatively unspecific listings and may account for their low rate of response. The 1,150 questionnaires were distributed during September and October 1978. By December 20, 1978, we received 228 useable responses, representing a response rate of 19.8%. That figure compares favorably with reported average mail response rates (8). The response rate was highest among professors of psychiatry (31%), followed by deans (14%) and residents (12%).

RESULTS

Our questionnaire consisted of 6 divisions, which are summarized with their responses.[1]

1. Importance of psychic studies to future graduates. Fifty-eight percent of the respondents believed that an understanding of psychic phenomena is important to future graduates of psychiatry programs, compared to 22% who considered it unimportant. An additional 17% were neutral, and 4% were undecided. Opinion was mixed, however, regarding psychic studies in nonpsychiatric education, with the majority viewing that need as unimportant or remaining neutral.

2. Need for research on nonmedical factors in healing. More than half of the respondents (52%) believed that additional research is needed in this area, 35% were neutral, 4% were undecided, and 8% believed that additional research is not needed. In short, there was a strong consensus on such need, with no significant differences among sample groups.

3. Importance of specific healing factors. Nature's own reparative processes were rated as important factors in healing by 97% of the respondents; appropriate diagnosis was rated important by 96%. The patient's expectations, faith, and cooperation followed closely (94%), with specific medical-surgical intervention in fourth place, surprisingly (92%). Those leaders were followed by very high rates for the practitioner's therapeutic personality, 90%, and the power of suggestion, 82%. Another higher than expected percentage (44%) believed that psychic factors, i.e., some kind of unknown augmentation of the healing process, were important. Energy-field transfer from practitioner to patient was perceived as important by the smallest percent (11%). However, about half of the respondents were neutral or undecided about this factor, seemingly indicating ambivalence or some uncertainty about the meaning of the term "energy-field transfer."

4. Forms of psychic phenomena. Respondents were asked whether they believed that academic study of 12 specific psychic phenomena would be valuable. There was considerable variation in perceptions, possibly due in some cases to definitional uncertainty. Voluntary control over autonomic functions (biofeedback, etc.) and transcendental or religious meditation received the highest percentages of positive responses (39% and 21%, respectively). Mind control, psychic healing, psychokinesis, ESP, mysticism, nonpsychotic hallucinations, survival after death, and cosmic states of consciousness each received positive responses from 5% to 12% of the respondents. Reincarnation and energy fields received support from less than 5%. There was agreement among the respondent groups in all of the above areas except nonmedical healing, which, interestingly enough, professors of psychiatry accepted more than either psychiatric residents or medical school deans.

5. A proposed psychic aptitude test as a diagnostic instrument. Thirty percent believed such a test would be useful as a diagnostic aid, 43% felt it would be useless, and 27% were neutral or had no opinion.

6. Demographic prevalence of psychic phenomena. Relatively few respondents (15%) denied the existence of psychic abilities, latent or overt. Most (42%) acknowledged the possibility of their existence. Twenty-one percent believed that some people possess psychic abilities in some degree, and 14% believed all people possess them in some degree. The remainder were neutral. In addition, 35% had themselves or knew of someone who had had occult or paranormal experiences, chiefly ESP, telepathy, precognition, and altered states of consciousness.

DISCUSSION

Our survey was intended to serve two functions: providing directions for further research and indicating current attitudes about psychic phenomena in education. We believe that despite certain shortcomings in any questionnaire of this kind, the opinions of 228 working scientists, the majority of whom are academic administrators, have intrinsic value.

Our results indicate a high incidence of conviction among deans of medical schools and psychiatric educators that many psychic phenomena may be a reality, psychic powers are present in most or all of us, nonmedical factors play an important part in the healing process, and, above all, studies of psychic phenomena should be included in psychiatric education and, to a lesser extent, in other branches of medicine. The relatively high percentage of neutral and undecided opinions suggests that the attitudes of many are still open but cautious. This seems to indicate that their attitudes may become increasingly supportive as interest becomes more manifest—a hypothesis that awaits further research and trend analysis.

Would the inclusion of psychic studies add to the scope of psychiatry and attract more medical students

[1]Percentages are rounded off to the nearest whole number. Copies of the questionnaire and tables of the responses are available from the authors on request.

o the profession? We believe it would. In the past few ears there has been a substantial progressive drop in he percentage of medical students entering psychiary—a reduction of more than 12%. According to ardes, "The nature of the educational experience ofered the student is one of the major factors. . . . Admissions committees must recognize the importance of he *psychosocial, humanistic* side of medicine (italics dded). . . . Psychiatry has to elaborate more clearly n the precise role of psychiatrists vis-à-vis other medcal specialties by enlarging the armamentarium of sychiatric clinical approaches" (9). In short, our profession must expand its horizons to include important, resh dimensions. We submit that psychic studies are t least one such dimension and trust that our findings vill provide useful information to educational decision nakers in planning a comprehensive, contemporary ealth care curriculum in keeping with the times.

Consultees' Representations of Consultants' Psychiatric Diagnoses

BY ALLAN L. CALLIES, MICHAEL K. POPKIN, M.D., THOMAS B. MACKENZIE, M.D., AND JAMES MITCHELL, M.D.

In an attempt to characterize consultees' representations of consultants' psychiatric diagnoses, the authors reviewed the medical records from 190 psychiatric consultations in a general hospital. Using specific outcome criteria, they rated 50% of representations as concordant and 39% as nonconcordant. Five variables, including the primary medical diagnosis at discharge and the referring service, were significantly related to concordance. Surprisingly, concordance was independent of the psychiatric diagnosis, indicating that consultees did not respond differentially to varying magnitudes and implications of the different disorders. This work raises the question of possible strategies to improve receptivity to psychiatric diagnoses in the consultation setting.

Efforts to measure the effectiveness of psychiatric consultation in the medical-surgical hospital should address the responses of the consultee as initial arbiter of the consultant's perceptions. We have previously characterized consultees' responses to the recommendations of psychiatric consultants with regard to psychotropic drugs (1) and diagnostic actions (2). As a further step in the development of our Consultation-Liaison Outcome Evaluation System, which we designated CLOES, in the present study we examined consultees' representations of consultants' psychiatric diagnoses.

METHOD

We retrospectively examined consultations performed by the Adult Psychiatric Consultation-Liaison Service of the University of Minnesota Hospital during the period January–June 1977. The service provides psychiatric interventions, support, and diagnostic skills to the medical, neurological, and surgical inpatient services of the hospital. A member of the requesting service is contacted, if possible, before and after the initial patient evaluation. These contacts are intended to clarify the reasons for the request and subsequent impressions. Whenever possible, the patient is seen within 24 hours of submission of the request. After the initial interview a handwritten evaluation is placed in the progress notes of the medical chart. Although a specific format is not used, the resultant psychiatric diagnosis is usually placed at the end of the note. The written consultations were authored by the service's attending staff, third- or fourth-year residents, or others serving in an emergency capacity. The principal diagnostic nosology used by the service at the time of the study was *DSM-II*.

We reviewed the medical records of patients seen by the service during the study period. For each case we identified and recorded all psychiatric diagnoses offered by the consultant in the initial note. We then screened the discharge summary for the same hospitalization (dictated by a house officer and signed by the attending physician) for the consultee's representation of each psychiatric diagnosis. Each case was rated as follows: nonconcordant if no mention of the diagnosis was made; concordant if a verbatim or near verbatim representation of the consultant's diagnosis was found; and uncertain if the representation was not rated concordant or nonconcordant.

For each case rated uncertain, a second procedure followed. Each psychiatric diagnosis offered by the consultant and the corresponding representation by the consultee were presented independently to two psychiatrists who were not members of the service during the study interval. Each representation was rated according to the following criteria: concordant if it accurately conveyed the descriptive portion of the diagnosis, such as affective disorder or organic brain syndrome, and if it included modifying statements judged critical to understanding the severity or implications of the disorder; partially concordant if the descriptive portion was correct but a critical modifier was absent; and nonconcordant if the descriptive portion was inaccurate. In those cases in which the consultant offered more than one diagnosis, the case was given the rating of the least concordant representation. This procedure was repeated 72 hours later with an altered sequence of case presentations. Raters had not been informed of the repetitive design of the study.

Received June 11, 1979; revised Nov. 13, 1979; accepted Nov. 15, 1979.

FIGURE 1
Final Concordance Assignments on 200 Psychiatric Consultations[a]

[a]C=concordant, U=uncertain, PC=partially concordant, and NC=nonconcordant.

Thus, a total of four ratings was available for each case initially classified as uncertain. Each rating was scored according to the following system: concordant=+1, partially concordant=0, and nonconcordant=−1. Final concordance assignments for each case were based on the composite score of the four ratings: 4 and 3=concordant; 2, 1, 0, −1, and −2=partially concordant; and −3 and −4=nonconcordant.

Consultees' concordance was then examined as a function of 20 variables that characterized the patient, consultee, consultant, or the consultation (see table 1). Individual chi-square analyses or t tests were used to identify those variables which were significantly ($p<.05$) related to concordance with consultants' psychiatric diagnoses.

RESULTS

Of the 200 consultations performed in the study interval, 190 (95%) were reviewed. Records for four cases had not been retrieved three months after they were requested and were excluded from the present analysis. Six cases that resulted in inpatient psychiatric transfers were also excluded. Of the remaining 190 consultations, 68 (36%) were initially rated uncertain. Forty-eight of these cases were subsequently assigned a concordant or nonconcordant rating. All four component ratings were identical in 39 of these cases. After concordance ratings were assigned to the uncertain cases, the overall results (N=190) yielded 95 cases of concordance (50%), 20 cases of partial concordance (11%), and 75 cases of nonconcordance (39%). Of the 75 cases of nonconcordance, 51 (68%) failed to include the psychiatric diagnosis in the discharge summary and 24 (32%) contained inaccurate representations (see figure 1). To highlight the differences between concordant and nonconcordant cases, the 20 partially concordant cases were eliminated. Thus, subsequent statistical analysis involved 170 cases of which 95 (56%) were rated concordant and 75 (44%) nonconcordant.

Of the 20 variables examined (see table 1), 5 were significantly related to concordance. They were primary medical diagnosis at discharge, consultee service, days hospitalized at time consultation was performed, days hospitalized after consultation was performed, and total days hospitalized. Concordance rates for these variables are detailed below. With respect to primary medical diagnosis at discharge, a concordance rate of 79% was observed when the consultee's diagnosis was functional, compared with 50% for all other diagnoses combined ($\chi^2=7.60$, $p=.006$). Concordance rates also differed widely according to referring service (i.e., 11% concordance in a general surgery group versus 63% in general medicine; $\chi^2=16.61$, $p=.001$). The concordant group averaged 3.9 fewer days hospitalized at time of consultation ($t=2.96$, $p=.004$), 3.3 fewer days after consultation ($t=2.00$, $p=.047$), and 7.2 fewer days in total ($t=3.00$, $p=.003$).

DISCUSSION

We assessed consultees' representations of consultants' psychiatric diagnoses in this study using discharge summaries from medical records. Written at the conclusion of the hospital sequence, the discharge summary recapitulates and offers perspective on the completed hospitalization. It sets forth the responsible physician's account of what has transpired, together with what has been determined or planned. Accordingly, the discharge summary may be expected to address such consultations as have been carried out. Such attention might ideally include the consultee's reflections on and integration of respective consultants' perceptions. Since diagnostics are pivotal in reasoned clinical management and disposition, the adequacy of consultees' diagnostic representations should constitute a critical outcome factor.

In only 50% of the discharge summaries reviewed were consultees' representations judged concordant with the psychiatric diagnoses made by consultants. Of those rated nonconcordant, two-thirds omitted the psychiatric diagnosis entirely and the remaining one-third provided inaccurate representations. Overall, more than one-quarter of the discharge summaries made no mention of the consultants' psychiatric diagnosis. These results, comparable to Froese's findings in a pediatric population (3), demonstrate that neither accurate consultee representation nor even inclusion of consultants' psychiatric diagnosis in discharge summaries can be taken for granted.

The surprisingly low overall concordance rate appears to involve two factors. First, the failure of consultees to include the psychiatric diagnosis in the discharge summary suggests that consultees perceive psychiatric diagnoses as having minimal usefulness or importance. Oversights aside, the omissions may also reflect disagreement, lack of comprehension, or a devaluation of the consultant's opinion. Second, when efforts at representation are made, the failure to depict accurately the consultants' diagnosis calls into question consultees' grasp of psychiatric nosology. Errors of omission occurred twice as often as inaccurate representations. Taken together, the omissions and inaccuracies reflect the wide latitude for improvement in consultant-consultee communication. This is especially so given our emphasis on dialogue with the consultee both before and after initial patient evaluation.

The examination of selected patient, consultee, consultant, and consultation characteristics (table 1) identified five variables that were significantly associated with consultees' diagnostic concordance. Among these was the consultee's primary medical diagnosis at the time of discharge. A concordance rate of 78.8% emerged for functional disorders (26 of 33 diagnoses), versus 50.4% for all primary medical diagnoses combined (69 of 137 diagnoses). This striking difference demonstrates a heightened receptivity to psychiatric diagnosis when the consultee has been apparently unable to identify or document pathophysiology. At such a juncture, it appears that psychiatric diagnosis suddenly achieves credibility, perhaps vindicating the absence of organic findings and confirming the consultee's diligence. Most distressingly, this sequence appears to indicate that consultees employ a functional-organic dichotomy in their conceptual and clinical approach to patients and tend to diagnose psychiatric disorder by exclusion.

A second variable found to be related to concordance with consultants' psychiatric diagnoses was the consultee's service (e.g., medical, surgical, neurology). Concordance rates differed strikingly by service, from a disturbing low of 11.1% in a general surgery group (2 of 18 diagnoses) to 63% in a general medicine group (34 of 54 diagnoses). These findings may be indicative of intrinsic differences in specialty training with respect to both psychiatric disorders and their implications. Most nonconcordant responses in the surgery group consisted of omissions rather than inaccuracies. One might argue that these omissions represent no more than a problem in documentation; however, it is more probable that they represent oversight or haste. In our studies of concordance with consultants' recommendations for psychotropic drugs (1, 4) and diagnostic actions (2), we did not find that responses differed by type of consultee service. This seems to imply that the response of the surgical consultees in this study is specific to psychiatric nosology and its representation, rather than embodying a more general response to actions of psychiatric consultants. It may be that the low concordance of the surgical group involved a question of the perceived relevance of diagnostic labeling when unaccompanied by clinical actions. Surgeons' lack of interest or their discomfort regarding psychiatric diagnosis merits further study.

The remaining three variables associated with concordance involved the patient's length of stay. Patients representing concordant cases averaged fewer days of hospitalization at the time of consultation than did patients representing nonconcordant cases. They also spent fewer days in the hospital after consultation and had fewer total days of hospitalization. These data suggest that the more quickly consultees perceive the need for psychiatric intercession, the more receptive they are to the resulting observations of the consultant. Having promptly recognized psychopathology, consultees may find psychiatric diagnoses more useful or tenable. Although this may represent another facet of the consultees' reliance on a functional-organic dichotomy, it cannot be said to involve psychiatric diagnosis by exclusion. Patients with lengthier post-consultation and total hospitalization periods may be at risk for omission of psychiatric diagnosis or inaccurate representation due to the time lag from consultation to discharge. It should be noted that our previous studies have found heightened concordance phe-

nomena when the consultation occurred early in the hospitalization.

Of the 20 variables we examined, 15 exhibited no significant relationship with concordance. These variables included the resultant psychiatric diagnosis itself, the patient's psychiatric history, the consultant's identity and status, and the presence of and concordance with other recommendations of the psychiatric consultants. It is possible that a larger sample might reveal relationships not appreciated in the present study. Factors not explored here, such as the clarity, uniformity, and brevity of the consultant's presentation, may prove to be important determinants of consultees' representations of psychiatric diagnoses. It should also be emphasized that this study did not concern itself with the accuracy of the consultants' diagnoses.

One finding that should be particularly emphasized is that consultees' concordance with consultants' diagnoses is not related to the resultant psychiatric diagnosis in question. This finding appears to point to a generalized lack of interest or discomfort regarding psychiatric nosology rather than toward differences in the perceived usefulness of specific diagnostic entities or differences in the presentation of diagnostic statements. The overall concordance rate of 50% in this study is comparable to that reported in an earlier study of concordance by case with consultants' recommendations for diagnostic action (2) but appears somewhat lower than the overall 68% concordance found with consultants' recommendations for psychotropic medications (1). This implies that consultees may be more concerned with management than with evaluation and assessment.

This work extends our quantitative description of consultees' response to psychiatric consultation and anticipates the development of specific consultation strategies incorporating or derived from quantitative outcome studies. For example, this might include major revisions or simplifications of our nosological schema. The results should be contrasted with consultees' representations of diagnoses made by consultants from other medical specialties. They demonstrate several major challenges confronting the psychiatric consultant in the general hospital and reflect the opportunity for marked improvement in the accomplishment of consultant task functions. The findings also speak to the hazards of assuming either adequacy of communications or shared conceptual frameworks between consultant and consultee. This may be particularly instructive with the advent of *DSM-III*.

CLINICAL AND RESEARCH REPORTS

This section contains 1) new research findings, including preliminary data from pilot studies, either clinical or laboratory; 2) worthwhile replication studies; 3) case reports that describe a truly new syndrome or cast new light on established ones; and 4) case reports that indicate a new therapeutic procedure of potential value or call attention to adverse effects of drugs or previously unreported complications of therapeutic interventions. Program descriptions and literature reviews cannot be printed in this section. Criteria for format are listed in "Information for Contributors" in each issue; papers that do not adhere to these criteria will be returned to the author.

Effect of Psychiatric Intervention on Use of Antihemophilic Factor Concentrate

BY H. ALLEN HANDFORD, M.D., DENNIS CHARNEY, M.D., LARRY ACKERMAN, M.D., M. ELAINE EYSTER, M.D., AND EDWARD O. BIXLER, PH.D.

The development of antihemophilic factor (Factor VIII) freeze-dried concentrate, which can be infused by patients outside a hospital, has radically changed the care and treatment of hemophilic patients. With the advent of home treatment, however, the staffs at hemophilia centers who provide Factor VIII concentrate and monitor hemophilia treatment programs have observed that the amount of Factor VIII concentrate used varies widely among patients, even when the patients have comparable levels of severity of the disease and frequency of bleeding.

The potential effect of emotional status on a patient's use of Factor VIII concentrate is suggested by Agle and Mattson (1), who discussed the psychological component of hemophilia. They emphasize the importance of understanding the hemophilic patient's relationships with his family, home, work, and social environments, and they encourage psychiatric intervention when indicated. Similarly, LaBaw (2) reported the successful use of suggestibility and hypnosis in controlling the pain and bleeding of hemophilia.

The purpose of our study was to evaluate the effects of emotional status on a patient's use of Factor VIII concentrate by assessing the relationship between psychiatric intervention and a patient's use of Factor VIII concentrate over a given time period. In the following case report we describe an adolescent with severe hemophilia, and we compare the levels of Factor VIII concentrate he used during three 15-month periods of time—before, during, and after psychiatric intervention. We analyzed these data by using the Time Series Analysis originally described by Box and associates (3, 4). The model fitting and analysis were done with a computer program developed by Glass and associates (5). These methods have been found appropriate for statistical analysis of large quantities of data that relate to a single subject and have been gathered over time. For each 15-month period of time we also compared by month the number of bleeding episodes the patient experienced, his total number of Factor VIII concentrate infusions, and the number of days he was infused.

We found that this patient reduced his use of Factor VIII concentrate during and after the psychiatric treatment phases, which suggests that psychological factors affect Factor VIII concentrate use and that patients with severe hemophilia may benefit from psychiatric intervention.

Case Report

When first referred for psychiatric evaluation, the patient was a 15-year-old with severe classic hemophilia who had a Factor VIII level of less than 1% (normal range, 50%–150%).

TABLE 1
Antihemophilic Factor (Factor VIII) Concentrate Use in a Hemophilic Adolescent Who Received Psychiatric Intervention

	Monthly Factor VIII Concentrate Determinations					
			Number of Infusions			
15-Month Periods	Total (U)	Corrected for Weight[a] (U/kg)	Total	For Hemorrhage	Days Infused	Number of Bleeding Episodes
Baseline	22,680	426.6	23.3	5.5	22.5	2.4
During intervention	15,008[b]	283.1[b]	17.3[b]	2.7	16.9[b]	1.5
After intervention	12,970[b]	229.5[b]	16.0[b]	2.4[c]	15.5[b]	1.4[c]

[a]Body weight factor was linearly interpolated between actual weighings.
[b]Significantly different from baseline, $p<.01$.
[c]Significantly different from baseline, $p<.05$.

Before age 10 he had often been confined to a wheelchair because of frequent and severe bleeding. After he was placed on regular treatment with Factor VIII concentrate at age 10, however, he became active in tennis and swimming. Our hematology staff noted that he was using an excessive amount of Factor VIII concentrate, presumably out of anxiety and fear of bleeding rather than simply for the bleeding episodes as they occurred. At this point he was referred for psychiatric evaluation and possible treatment.

A mental status examination revealed that the young man was anxious about possibly having to reduce his use of Factor VIII concentrate. He had pressure of speech but no thought disorder. His memory was good, and he was well oriented in all spheres. His thought content revealed some adolescent conflicts about dealing with parental anger, meeting girls, and coping with teachers. He denied being unusually worried about his bleeding, and some disorganization under stress was noted.

The patient's mother was concerned that less frequent Factor VIII concentrate treatment would jeopardize the nearly normal lifestyles the patient and his family had been able to develop. Her husband expressed similar concerns that less frequent infusions would result in their son having more frequent bleeding incidents. Psychiatric intervention was offered, and the young man and his family were fully cooperative. All sessions were conducted by the same psychiatrist, who remained blind to the patient's Factor VIII concentrate use. Other medical staff exerted no pressure on him or his family to reduce concentrate use.

During the 15-month period before psychiatric intervention the patient administered Factor VIII concentrate to himself 5–6 days each week; he used almost four times as much concentrate as did the average home-therapy patient in our hemophilia program. His baseline mean (±SEM) of Factor VIII concentrate use was 22,680±994 U/month. In this program state funds provide for the total cost of Factor VIII concentrate used by each patient, without regard to financial circumstances, and federal funds provide for psychiatric and other staff services.

The patient then received 15 months of psychiatric treatment. The treatment began with 7 family therapy sessions over a 3-month period with an emphasis on the development of communication skills and the open expression of feelings and problems among family members. His Factor VIII concentrate use for this period dropped to 19,367±1,755 U/month, a 15% reduction from baseline. During the next 4 months, one of his siblings was depressed and was seen in 14 individual psychotherapy sessions. The patient's mean Factor VIII concentrate use during this period was 14,796±895 U/month, a 35% decrease from baseline. Three more family therapy sessions were held during the next 2 months; the main theme was the young man's separation and independence from his family. His use of Factor VIII concentrate for this period increased slightly (5%) over the preceding 4 months to 15,897±10 U/month. Over the next 4-month period he participated in 5 adolescent group therapy sessions in which the main themes were dating and jobs. His mean Factor VIII concentrate use for this period was 13,364±848 U/month, a decrease of 41% from baseline. After 3 self-hypnosis sessions during the next 2 months, his psychiatric treatment was discontinued. His Factor VIII concentrate use for this final treatment period was 11,295±1,719 U/month, a decrease of 50% from the baseline mean.

Communication among family members improved during this 15-month treatment period. Feelings of optimism replaced those of depression in all of the family members. In addition, the patient learned to use self-hypnosis techniques at times of stress, such as before school examinations or when he sensed impending bleeding episodes. Subsequently, he made a successful college adjustment while living away from home.

During the 15 months following termination of psychiatric therapy, his use of Factor VIII concentrate rose slightly to a final mean figure of 12,970±621 U/month, for an overall reduction of 43% from the original baseline. As shown in table 1, throughout the study the patient showed a decline in the amount of Factor VIII concentrate he used per kilogram of body weight (corrected for weight gain), the number of hemorrhages he had, the number of infusions he used for hemorrhage and nonhemorrhage episodes, and the number of days he used infusions.

Discussion

Over the 15-month period of psychiatric treatment, this young man significantly reduced his excessive use of Factor VIII concentrate. This resulted in appreciable savings to the family and our program (approximately $10,885 after deducting psychiatric costs) without compromising his care and treatment or interfering with his activity level. Moreover, he maintained his reduction in Factor VIII concentrate use for 15 months following the end of psychiatric intervention.

Factors other than the effects of psychotherapy may have played a role in reducing this patient's Factor VIII concentrate use. We may have observed the Hawthorne effect, where any new therapy brings about change because of the novelty of the intervention as suggested by LaBaw (2) in his work with hemophilic patients. Also, the patient's desire to

please his therapist may have caused a reduction in his use of concentrate. It is our belief, however, that his continued low rate of Factor VIII concentrate use during the 15-month follow-up period substantiates the effectiveness of psychotherapy in reducing his use of Factor VIII concentrate.

We believe that as the patient's activity levels increased through the use of Factor VIII concentrate treatment, which he used in anticipation of bleeding rather than after its onset, he and his family began to rely on Factor VIII concentrate until he used the concentrate almost without limit to reduce his fear of bleeding episodes. When psychiatric intervention relieved this chronic stress in this patient and his family, he dramatically reduced his use of Factor VIII concentrate.

Psychotic Reaction Caused by Proprietary Oral Diet Agents

BY CHARLES B. SCHAFFER, M.D., AND MARTHA WELTY PAULI

Self-medication with over-the-counter oral diet aids is increasing. Several of these diet aids contain phenylpropanolamine as the active ingredient. Phenylpropanolamine is available without a prescription in a variety of weight reduction formulations such as Dexatrim and Permathene. These anorexic agents contain as much as 75 mg of phenylpropanolamine per dosage unit; most contain 25–50 mg (1). The American Medical Association (2) reports that phenylpropanolamine is probably an ineffective anorexic agent. Phenylpropanolamine is also one of the most frequently used oral nasal decongestants, usually marketed in combination with an antihistaminic drug. Acute psychotic episodes in three patients following their use of phenylpropanolamine as an oral decongestant were reported by Kane and Greene (3); and Wharton (4) reported one case of paranoid psychosis related to the use of phenylpropanolamine as a nasal decongestant. To our knowledge there are no reports of psychotic reactions secondary to the use of phenylpropanolamine as an oral anorexic agent currently available in the literature. In the case report below we describe a woman who experienced a psychotic episode while taking oral diet aids.

Case Report

Ms. A was 23 years old, married, and the mother of one child. She was brought into the psychiatric emergency service by her husband and sister because she had been taking too many "diet pills." About five days before her admission she began taking one or two pills a day to lose weight. She had purchased these pills over the counter at a local drug store. About three days before her admission she began taking copious amounts of these pills. During that time she began to sleep less and displayed a change in behavior that included making bizarre statements, feeling people were going to harm her, running out of her house without a specific destination, and allowing the maintenance of her house to decline.

According to her husband and sister Ms. A had no previous similar episodes or psychiatric history, and she had functioned well as a mother and housewife. She had no recent episode of depression nor a history of significant drug or alcohol usage. There was no positive family psychiatric history.

When Ms. A was brought to the hospital she was noted to be alert but disoriented and somewhat agitated. Her speech was sparse and her thoughts were disorganized. She made several inappropriate responses to questions. Her attention and concentration were impaired; her judgment and insight were poor. At times she giggled and at other times she was combative. She also made some fragmented paranoid statements. She was admitted to the hospital, and her family was asked to bring in the diet pills she had been taking. Her husband brought in a bottle of Permathene and a bottle of Dexatrim. He believed that his wife had been taking 3–5 pills a day from each bottle during the few days before her admission.

On the first day of hospitalization Ms. A remained dis-

organized and disoriented, and she displayed regressive, intrusive, hyperactive behavior requiring restraints. After 3 days of hospitalization her symptoms improved and she was considered by her husband to be her normal self. She was not given any daily medication during this period.

We ordered routine laboratory tests at the time of Ms. A's admission (electrolyte, BUN, creatine, calcium, phosphorus and glucose levels, complete blood count, and liver function tests); all of these were within normal limits. Ms. A did not cooperate for a physical examination when she was admitted, but she did cooperate later and there were no remarkable physical findings.

Discussion

The acute psychotic episode experienced by this patient was most likely related to the ingestion of more than the recommended amount of the oral anorexic agents Dexatrim and Permathene. Ms. A's psychiatric symptoms began shortly after her indiscreet self-medication, and her symptoms resolved quickly without treatment after these agents were discontinued. She lacked any history of primary psychiatric disorder that might have played a role in the production of her psychotic symptoms. The drug-induced psychosis secondary to amphetamine use is widely publicized and well known (5). However, there is much less awareness about similar, if less frequent, complications of the amphetamine-related compounds, the sympathomimetic amines. There have been two reports of psychosis caused by ingestion of the sympathomimetic amine ephedrine (6). Even though phenylpropanolamine is regarded as one of these agents with fewer central nervous system effects, it should be noted that it is not without hazard. A pharmacy reference warns that untoward central nervous system effects, such as nervousness, restlessness, insomnia, and headache, may occur with the use of phenylpropanolamine (7), but there are no warnings of possible psychotic reactions even with excessive usage. Likewise, there are no warnings on the packages of Dexatrim or Permathene of possible psychotic reactions with excess use.

Caffeine is also an ingredient in Permathene (75 mg phenylpropanolamine, 140 mg of caffeine) and Dexatrim (50 mg phenylpropanolamine, 200 mg of caffeine). It has been reported that a high intake of caffeine (caffeinism) can cause symptoms such as nervousness, irritability, tremulousness, and insomnia, but there have been no reports of psychotic symptoms resulting from an excess intake of caffeine (8), even when up to 5,000 mg/day is taken. It is therefore unlikely that caffeine played a role in our patient's psychotic episode.

The wide use of phenylpropanolamine as a proprietary decongestant for colds, hay fever, and sinusitis, plus its increasing use as an oral over-the-counter anorexic agent, indicates a need to increase our awareness of its possible serious psychiatric side effects, including psychotic reactions. Indeed, the risks of these anorexic agents as diet aids may outweigh their benefits because there is no reliable evidence that phenylpropanolamine can help obese patients achieve a long-term weight reduction (9).

Elevated Platelet Monoamine Oxidase Activity in Patients with Nonendogenous Depression

BY KERRIN WHITE, M.D., JEAN SHIH, PH.D., TSE-LING FONG, HELEN YOUNG, PH.D., RONALD GELFAND, M.D., JEFFREY BOYD, PH.D., GEORGE SIMPSON, M.D., AND R. BRUCE SLOANE, M.D.

Platelet monoamine oxidase (MAO) activity has attracted psychiatric research because the enzyme's role in metabolizing neurotransmitter amines ties it into biochemical theories of psychopathology and psychotropic drug effect. Increase or decrease of MAO activity may lead to depletion or accumulation of brain amines; conversely, excess or deficiency of these amines from other causes may lead to inhibition or enhancement of enzyme activity. MAO activity in blood platelets has received most psychiatric study because we have easier access to this tissue than we have to the brain. The case for the relevance of platelet MAO assay to psychopathology rests mainly on empirical findings of altered activity in various psychiatric conditions.

The greatest amount of research has focused on patients with schizophrenia, in whom the majority of studies have found lower MAO activity than in normal control subjects (1). However, low MAO activity has been reported in several other disorders including bipolar manic-depressive illness (2, 3).

In contrast, higher than normal MAO activity has been reported mainly in depressive patients outside the bipolar group (2–8). However, patients with unipolar depression comprise a large, heterogeneous group, and which of these patients may show elevated enzyme activity remains a major question. Orsulak and associates (8) singled out a syndrome they named schizophrenia-related depressions, which may relate more closely to character disorder than to schizophrenia, although their diagnostic category certainly denotes a chronic disorder. Robinson and associates (5) found that patients with high-MAO depression were more symptomatic and less responsive to treatment than other patients with depression. Landowski (6) reported that the elevation of MAO activity in patients with unipolar depression related to intensity of anxiety. These few findings suggest that elevated MAO activity may occur within the group of depressed patients sometimes labelled atypical or nonendogenous. One of the few dichotomies to emerge consistently from studies attempting to classify depressed patients on the basis of clinical data (9) is the separation of endogenous depressed patients from nonendogenous depressed patients. Therefore, it seems important to investigate this classification in relation to the biological parameters of affective disorder.

Method

Blood specimens were obtained from 96 subjects: 52 outpatients who met the Research Diagnostic Criteria (RDC) (10) for major depressive episode, 34 hospital staff matched roughly for sex and age (their specimens were drawn and analyzed concurrently with those of the outpatients), and 10 hospitalized patients with schizophrenia who were also diagnosed according to RDC. All RDC diagnoses were made by two clinicians. All specimens were drawn in the morning; the subjects had not taken medications for at least 1 week. The outpatients were further subclassified according to RDC as patients with bipolar depression, patients with nonbipolar endogenous depression, or patients with nonbipolar nonendogenous depression.

Platelet MAO activity was assayed according to the following procedure. First, 20 cc of whole blood was drawn from the antecubital vein into a plastic syringe; it was then transferred to a plastic tube containing 1 cc of 3.8% sodium citrate as an anticoagulant. The specimen was centrifuged at 600 rpm for 15 minutes and at 20,000 *g* for 5 minutes to yield a platelet pellet. The pellet was washed with 2 cc of 0.9% sodium chloride and spun again at 20,000 *g* for 5 minutes. After 2–8 weeks of storage at −20° C, the pellet was sonically treated in 1 cc of 0.05 M phosphate buffer (pH, 7.0). About 300 μg of the resulting protein was incubated with ^{14}C-phenylethylamine with a final concentration of 5 μM; after 30 minutes the reaction was stopped with 0.1 cc of 6 N hydrochloric acid. The mixture was passed through a 4.0×0.6-cm column of Rexyn 101-Na^+ and washed with 2 cc of water. The eluate was combined with 10 cc of Aquasol and counted in a Beckman LS-335 liquid scintillation counter using automatic external standardization. Enzyme activity was expressed as nanomoles of the product formed per milligram of protein per 30 minutes.

TABLE 1
Demographic Characteristics and Mean Platelet MAO Activity in 62 Patients with Schizophrenia or Depression and 34 Control Subjects

Diagnostic Group	Male to Female Ratio	Age (years)		MAO Activity (nmol/mg protein/30 minutes)					
				Men		Women		Total	
		Mean	SD	Mean	SD	Mean	SD	Mean	SD
Schizophrenia (N=10)	1:1	36.7	15.2	0.42	0.33	0.52	0.20	0.47	0.26
Bipolar depression (N=10)	1:1	28.1	8.3	0.40	0.22	0.45	0.18	0.43	0.19
Endogenous depression (N=7)	0.75:1	36.7	14.8	0.29	0.18	0.56	0.33	0.44	0.24
Nonendogenous depression (N=35)	1.5:1	34.7	9.4	0.44	0.22	0.66	0.33	0.53	0.29
Control (N=34)	1.1:1	34.0	11.1	0.37	0.16	0.45	0.18	0.41	0.17

Results

Table 1 shows means and standard deviations of platelet MAO activities for the diagnostic groups, broken down by sex. In all cases, analysis of covariance was employed; sex, age, race, and diagnosis were treated as covariants when appropriate. Overall, women had a significantly higher enzyme activity than men, $F(1,91)=7.58$, $p<.007$. Women also showed higher mean activity than men within each diagnostic group, although this difference reached statistical significance only for patients with nonendogenous depression, $F(1,32)=9.52$, $p<.004$. For all subjects age showed a significant positive correlation with MAO activity ($r=0.24$, $p<.01$). We failed to show any consistent relationship between race and enzyme activity, $F(3,89)=0.42$, $p>.7$. In comparing the various groups, statistically significant differences emerged only between those patients with nonendogenous depression and the control subjects, with the depressed patients showing higher than normal MAO activity, $F(1,67)=5.50$, $p<.03$. Interestingly, this diagnostic difference held true for the women, $F(1,26)=8.71$, $p<.007$, but not for the men, $F(1,35)=0.82$, $p>.3$.

Discussion

Our results support the hypothesis that elevation of MAO activity may occur in the group of patients with nonendogenous depression. The limitation of this finding to women raises the possibility of a relationship between menstrual variations in depressive symptoms and MAO activity (4); however, we lack the data to confirm this. We note that our results are consistent with prior reports of higher enzyme activity in women than in men and of enzyme activity increasing with age (5). Although we failed to replicate the findings of other researchers who showed that patients with schizophrenia have lower enzyme activity, we note the small size of our schizophrenic patient group and the fact that we compared inpatients with schizophrenia to outpatients with other diagnoses.

Our finding of a biological alteration in patients with nonendogenous depression has special interest. This group of patients, normally associated with the less specifically defined group of neurotic depressed patients, has also been generally associated with psychological rather than biological etiology and treatment (9). Thus, patients with nonendogenous depression have received correspondingly less attention in biological research than patients with endogenous depression. Our findings call this tendency into question. Moreover, these findings raise the intriguing possibility that elevated MAO activity is related to the responsiveness of patients with nonendogenous depression to MAO-inhibiting antidepressant medications.

However, nonendogenous depression remains a category only fractionally smaller than unipolar depression as a whole. Also, the enzyme activity findings of our patients with nonendogenous depression overlapped considerably with those of all other diagnostic groups. In order to find a closer correlation between elevated MAO activity and depressed patient subtypes, we may need more phenomenological studies contrasting the clinical features of depressed patients with high versus low MAO levels.

Neuroendocrine Dysfunction and Blood Levels of Tricyclic Antidepressants

BY JUAN RAMON DE LA FUENTE, M.D., AND ALAN H. ROSENBAUM, M.D.

There is increasing interest in developing scientific laboratory procedures to help psychiatrists document their clinical impressions and to make their therapeutic interventions more rational. Psychoendocrine strategies (1) and determination of plasma concentrations of psychotropic drugs (2) appear most promising.

Despite significant advances in classification and pharmacologic treatment of affective disorders, precise documentation of depression in adolescent psychiatric populations remains conspicuously absent (3). Traditional views of adolescent turmoil and phenomenologic features somewhat distinct from those of depression in adults seem to have contributed to this state of affairs (4). Adolescents with affective illness, like the subject of our case report, present an opportunity to test the clinical value of laboratory aids, particularly when such adolescents exhibit phenomenologic features that do not fit the usual pattern of a major affective disorder.

Case Report

Malcolm, a 16-year-old boy who was the product of a second marriage of both parents, came to our hospital with a 2-month history of abnormal behavior and changes in his mental functioning. He had been examined at a local hospital, where the diagnoses of catatonic schizophrenia, acute organic brain syndrome, and possible seizure disorder had been made. Malcolm had reportedly been in good health until the onset of his current illness, which was marked by rapid heartbeat, perspiration, and feelings of fear and anxiety. He had also begun to suffer from initial insomnia and subsequent confusion and inability to concentrate on his studies. Malcolm was first seen by his family physician and was given imipramine hydrochloride, 25 mg orally at bedtime, and flurazepam hydrochloride, 15 mg orally at bedtime. He improved slightly for 4 or 5 days, but then all of his symptoms recurred and in a more aggravated form. His parents noted that he was becoming more withdrawn, fearful, and overly concerned about irrelevant matters. While on a trip with his father, Malcolm ran away because he thought that he was being taken away from his mother forever. He was subsequently admitted to another psychiatric facility. The facility's records described Malcolm as paranoid, with auditory hallucinations and convulsions. However, the symptoms were vaguely described, and neither Malcolm nor his parents were able to confirm them. Nevertheless, Malcolm occasionally complained of headaches and experienced dysphagia and twitching of the cheeks. Treatment with phenytoin sodium, primidone, and a small dose of haloperidol produced little improvement.

Interviews with the parents revealed that they had both suffered from periods of depression in the past. Malcolm's mother had responded well to lithium carbonate. Malcolm had always looked younger than his peers and when this difference became more apparent in 10th grade, he was teased by his peers and had fewer friends.

At admission, Malcolm was sleepy and did look younger than his stated age. He had sparse facial hair, his facies were somewhat masked, and his eyelids drooped slightly. A neurological examination revealed no significant abnormalities. Malcolm was oriented to time, person, and place, his speech was soft, his affect was very bland, and motor behavior was decreased. His cognitive functions were adequate. His thought content was marked by self-reproach, self-depreciation, and some rather vague nihilistic ideas, but Malcolm did not elaborate delusionally on any of these. He admitted that something was wrong with him and that he was not behaving as he should. He denied perceptual abnormalities.

Results of laboratory studies with extensive endocrine testing and tomograms of the sella were normal or negative unless otherwise specified. Malcolm's bone age was determined to be 14 years, and his plasma testosterone level was 2.5 ng/dl (normal range, 300–1,200 ng/dl). Three sequential EEGs showed no evidence of seizure activity. Using Jiang and associates' technique (5), we determined plasma corticosteroid levels. At 8 a.m. and midnight these levels were abnormally elevated (48 μg/dl and 40 μg/dl, respectively). The next day, after a 2-mg dose of dexamethasone given orally at midnight, the level was still elevated and showed minimal, if any, suppression (see table 1).

We used comprehensive psychometric, neuropsychologic, and personality assessments, including the Wechsler Memory and Intelligence Scales, Bender Visual-Motor Gestalt, Auditory-Verbal Learning Test, KNOX Cube Test, Tactual Performance Test, Kinetic and Static Steadiness, Rorschach Protocol, and MMPI, to rule out an organic brain disorder. However, these test results were inconclusive regarding the nature of Malcolm's psychiatric disturbance. Our working diagnoses were primary affective disorder and benign delay of adolescence. After completing the workup, we initiated treatment with imipramine hydrochloride. Plasma levels of the tricyclic antidepressant, determined according to Biggs and associates' method (6), were measured approximately 2 weeks later and were close to therapeutic range. We expected such a finding because Malcolm had improved considerably and showed total suppression after a new dexamethasone suppression test on hospital day 19.

However, Malcolm gradually regressed after a weekend visit with his mother. We slightly increased his dosage of imipramine hydrochloride and, despite what various authors (7–9) would consider therapeutic blood levels, his deterioration advanced and his ability to maintain suppression after

TABLE 1
Postdexamethasone Corticosteroid Levels in a Depressed Patient Treated Initially with Imipramine Hydrochloride and Then with ECT

Hospital Day	Plasma Corticosteroid Levels (ug/dl)		
	8 a.m.	4 p.m.	12 a.m.
2	48.0	12.0	35.0
19[a]	1.2	1.0	1.0
31[b]	1.8	9.2	16.0
44[c]	3.0	2.9	3.6

[a]Daily dose of imipramine was 75 mg; blood level of imipramine and desipramine, a metabolite of imipramine hydrochloride, was 174 ng/ml.
[b]Daily dose of imipramine was 85 mg; blood level of imipramine and desipramine was 264 ng/ml.
[c]After ECT.

another dexamethasone dose was impaired, showing an "early escape" from dexamethasone suppression on day 31. We discontinued imipramine hydrochloride on day 35.

Because of Malcolm's increasing withdrawal, recurrence of his ruminative self-depreciatory thoughts, and appearance of new dramatic symptoms (incontinence of feces and urine), we administered 7 sessions of ECT (series 7). Malcolm's improvement was as dramatic as his deterioration had been. He quickly became spontaneous and cheerful, even boisterous, engaging in some roughhousing. Before discharge, results of another dexamethasone suppression test showed that Malcolm had regained his ability to suppress.

Discussion

Malcolm's clinical presentation seemed to go beyond the border of a major affective disorder, as defined in *DSM-III*. However, he did have some psychiatric symptoms that, together with his family history of depression, an abnormal dexamethasone suppression test, and an initial response to tricyclic antidepressants, were suggestive of an affective disorder, albeit atypical.

The dexamethasone suppression test proved a valuable diagnostic aid in this case. Its ability to discriminate between depression and other psychiatric syndromes (mainly schizophrenia) is quite good (10) and thus could be of further benefit if used in larger samples of adolescents with confusing symptomatology.

An abnormal response to dexamethasone in a depressed patient should revert to normal when the patient's condition improves. This may be of additional value since the pharmacokinetic properties of tricyclic antidepressants have made interpretation of plasma concentration values within a therapeutic context very difficult. This test might be used to establish therapeutic dosages of antidepressants in nonsuppressor patients. Not all depressed patients are nonsuppressors and we are not suggesting routine monitoring by this means of all depressed patients; but for research purposes, this strategy might be worth pursuing.

In retrospective assessment of Malcolm's case, an accepted clinical practice would have been to increase the dosage of imipramine hydrochloride when Malcolm's condition deteriorated after his initial response to a modest dosage. However, when we considered the severity of the relapse, the length of the hospitalization, the increasing anxiety among the patient's relatives and the medical staff, and the presumably therapeutic blood levels of the medications, ECT seemed the most expedient approach. This case adduces further testimony that prediction of outcome on the basis of plasma concentration of tricyclic antidepressants is limited and that development of methods to identify high-plasma-concentration responders should receive priority in research.

Erotomania: A Separate Entity

BY MARIE RUDDEN, M.D., MARGARET GILMORE, M.D., AND ALLEN FRANCES, M.D.

Erotomania has been described in two different ways: as a secondary symptom of paranoia or schizophrenia, or as a distinct atypical psychosis. This case suggests the existence of a primary form of erotomania that manifests itself as a rare atypical psychosis most often reported in women with a characteristically intermittent and more benign course than schizophrenia.

Case Report

Ms. A., a 30-year-old professional woman, happened to meet an attractive man at a party and was very disappointed when he did not call her. She soon became convinced he was using car horns to communicate indirectly with her, was following her, tapping her phone, broadcasting her thoughts over the television, and wiring her bed to excite her sexually and to monitor her masturbation. Her work performance declined, she talked to walls, and begged her coworkers to stop relaying his messages. Ms. A held these beliefs almost continuously for a year and then reluctantly entered psychotherapy. She did not respond to phenothiazines and angrily stopped seeing her psychiatrist when he failed to confirm her suspicions.

Ms. A then consulted another psychiatrist and displayed prominent suicidal wishes and Schneiderian first-rank delusions but no derailment, hallucinations, or affective disturbance. She refused hospitalization and, in an effort to avoid involuntary commitment, requested an opportunity to confront her tormentor. At the meeting the "persecutor" denied Ms. A's charges and Ms. A's symptoms dramatically disappeared. She expressed considerable insight and relief, abandoned her delusions, and apologized with dignity. She has continued in outpatient psychotherapy and now functions well professionally without medication. She periodically develops delusions about various men she meets and about her male therapist. However, she is able to correct these delusions and to continuously maintain reality testing for a month or more at a time. Even when delusional, Ms. A shows a normal range of affect, a surprising warmth, maturity, and sense of humor. She is still often delusional about her male psychiatrist, claiming that he is monitoring her thoughts or indirectly communicating with her. However, she calls this her "daydream" and distinguishes the "part of myself that believes it." Sometimes she really does believe these delusions, especially when she is not in the psychiatrist's office.

When Ms. A was 8 years old, her father died after a prolonged illness. Ms. A had been his favorite daughter and for two years she was unable to accept the reality of his death. Instead she believed he might suddenly communicate with her or appear on the street. Eventually she was able to experience a delayed mourning. It is of interest that several other erotomanic patients reported in the literature had also lost parent figures in early childhood.

Ms. A had had a very active fantasy life as a child, but had no imaginary companions or transitional objects. As a woman, she has been somewhat shy but has experienced satisfying friendships and heterosexual relationships. She does not abuse alcohol or drugs and she gives no indication of factitious illness or malingering.

Discussion

Hollender and Callahan (1) divide erotomania into two types: 1) a primary form distinguished by the sudden onset of a delusional belief that focuses on one object and becomes a chronic, fixed delusional system; and 2) a secondary form in which the delusion has a gradual onset superimposed on other symptoms of schizophrenic psychosis. The first type is considered a subset of paranoia; the second of paranoid schizophrenia. Patients with both types of erotomania fail to respond to psychotherapy. Doust and Christie (2) collected eight additional cases, most of which fell into one of the above categories. Several cases with sudden onset were thought to be related to specific organic or toxic precipitants, but virtually all persisted chronically and were unresponsive to treatment. None of the patients had an intermittent course like the one Ms. A experienced.

Seeman's classification (3) differs from Hollender and Callahan's and includes a category that closely fits Ms. A. Seeman divides her patients into two groups: 1) women with constant, fixed delusions in conjunction with other symptoms of severe psychiatric illness, e.g., schizophrenia or schizoaffective disorders; and 2) women with recurrent and short-lived delusions in the absence of other symptoms of schizophrenia. The latter group of three women followed a characteristic and unusual pattern: they developed delusions about men they had actually met (rather than strangers) and often were able to give up their delusions when confronted by these men. Like Ms. A, these patients quickly repeated the pattern with a different man. They led active heterosexual lives, tended to be cyclothymic, competed with men, were better integrated than schizophrenic patients, and were diagnosed as having borderline personality, hysterical psychosis, or bipolar affective illness. In a personal communication to us, Dr. Seeman noted that one woman, who developed insight in therapy and had abandoned her delusions, would experience a recurrence when Dr. Seeman was on va-

cation and a male psychiatrist was covering her practice. When a female colleague provided coverage, the patient's delusions did not recur.

Raskin and Sullivan (4) described a woman who had been treated for affective illness and then developed a delusional system when her treatment ended. She believed her therapist was in love with her, monitored her activities, and tested her through the clinic staff. After three years of psychotherapy and phenothiazine treatment, she relinquished her delusions. Subsequently she occasionally retreated into erotic fantasies but was apparently able to test their reality. The authors concluded that erotomania can occur in women with varying levels of illness and ego functioning.

This brings us to the differential diagnosis of our patient. When first evaluated, Ms. A clearly met *DSM-III* criteria for schizophrenia, paranoid subtype, but her ability to correct the delusion with reality confrontation, and her normal affective range and interpersonal relatedness are not uncharacteristic of schizophrenia. Although her illness resembled paranoia, it did not meet the *DSM-III* criteria because of Ms. A's Schneiderian symptoms and because her delusions were not "unshakeable" and were more erotic than persecutory in content. Ms. A resembled patients with brief reactive (sometimes called hysterical) psychosis in the reactivity of her symptoms, heterosexual conflicts, and good premorbid functioning. However, the chronic course distinguished Ms. A's illness from brief reactive psychosis in which symptoms persist for no more than two weeks.

Ms. A's illness more closely resembles that of the erotomanic patients described by Seeman than any specific *DSM-III* category. She exhibits an intermittent delusional conviction of being sexually pursued by various men with whom she is acquainted. She had no affective disturbance and remains remarkably intact in other areas of personality functioning. The most unusual and specific aspect of her illness is her capacity to abandon delusions in response to reality confrontation. This suggests a particular deficit in her object relations and reality testing—a man must actually be present before Ms. A can test the reality of her perceptions about him. Investigators should examine the long-term efficacy of such reality confrontations. Only the collection of additional cases will determine to what extent this type of erotomania constitutes a rare, separate entity.

Serial Cognitive Testing in Cancer Patients Receiving Chemotherapy

BY THOMAS E. OXMAN, M.D., AND PETER M. SILBERFARB, M.D.

Previous research by our Cancer Psychiatry Division (1, 2) has suggested the need for an investigation of mild cognitive impairment in patients with cancer. Mild cognitive impairment may go undetected, yet it may influence a patient's ability to perform routine daily functions and to comply with treatment protocols. It was reported in one of these studies (2) that of 50 oncology patients who were admitted consecutively, those patients receiving chemotherapy demonstrated a significantly lower level of cognitive functioning than did nonchemotherapy patients. This was true regardless of the primary site of the cancer, whether there were cerebral metastases, or which chemotherapeutic agents were used. Despite these significant results several confounding variables were not controlled in the study, and they deserve closer scrutiny, namely, the existence of previous cognitive impairment and the possible effect of prior or concurrent brain irradiation (3).

In the present study we controlled for the above variables by testing each patient's cognitive capacity before chemotherapy treatment was begun, and we also eliminated from the study all patients who demon-

strated prior cognitive impairment. Also excluded from this study were patients who received radiation therapy. Serial cognitive testing was used, which made each patient his or her own control and allowed us to document a relationship between chemotherapy and cognitive impairment.

Method

As part of the cancer-psychiatry liaison service, patients admitted for chemotherapy to the oncology service of the Mary Hitchcock Memorial Hospital were seen routinely on rounds. From patients admitted consecutively we selected a group who demonstrated no obvious psychiatric illness or organic brain syndrome and asked them to participate in this study and to give informed consent. None of the patients had a history or symptoms of depression, mania, or schizophrenia using the criteria of Feighner and associates (4). We evaluated 20 patients; 3 patients were subsequently excluded because they received concurrent radiation therapy, 6 patients were excluded because they received follow-up care at distant locations, and 1 because he developed toxic septicemia immediately after chemotherapy.

The final study group consisted of 10 patients: 9 women and 1 man. The mean age was 52.8 years (range, 36-67 years). Eight of the patients had a high school education and the remaining two patients had some college education. Six of the women had adenocarcinoma of the breast; for the other 4 patients the primary sites of the disease were ovary (papillary adenocarcinoma), colon (adenocarcinoma), uterus (leiomyosarcoma), and prostate (adenocarcinoma). All patients had some evidence of metastatic disease, but the disease had not spread to the central nervous system. Five patients were having their first course of chemotherapy, and 5 were having repeat courses.

Eight of the 10 patients received intravenous doxarubicin with varying combinations of cyclophosphamide, cis-platinum, DTIG, and vincristine. One patient received cyclophosphamide, methotrexate, and fluorouracil and one patient received tamoxifen and bleomycin. Eight patients received haloperidol or perphenazine as antiemetics before and during chemotherapy (average neuroleptic dose, equivalent of 8 mg of haloperidol). Five patients received 100 mg of intravenous secobarbital before chemotherapy, and 5 patients received oral narcotics after the initial testing (average narcotic dose, equivalent of 17 mg of morphine per 24 hours).

Patients were tested for cognitive impairment before chemotherapy by the vocabulary, reading, and information subtests of the Wechsler Adult Intelligence Scale (5) and the Halstead-Reitan Battery (6). Four additional subtests of the Halstead-Reitan Battery (digit symbol, trails B, digit span forward, digit span backward) were used to determine the patients' sensitivity to mild cognitive impairment (6).

TABLE 1
Serial Cognitive Testing in 10 Cancer Patients Before and After Chemotherapy

Cognitive Test	Mean Raw Scores: Before Chemotherapy	After Chemotherapy: 24 hours	After Chemotherapy: 1 month	F[a]
Digit symbol	50.6	49.2	52.2	1.054
Digit span forward	6.1	6.3	6.3	.014
Digit span backward	4.3	4.0	4.4	1.83
Trails B	113.7	109.7	105.8	.153

[a]No analyses were significant.

Test results for all 10 patients before chemotherapy were within the norms expected for age and education, confirming the absence of significant cognitive impairment. The four subtests sensitive to mild cognitive impairment were repeated 24 hours after chemotherapy and 1 month after chemotherapy.

Results

Analysis of variance showed no significant difference on any of the subtests before chemotherapy, 24 hours after chemotherapy, or 1 month after chemotherapy (see table 1). These results were in agreement with clinical observations of these patients.

Discussion

A generalized interpretation of these results is limited because of the small number of patients in this sample and the possibility of a practice effect on serial testing (particularly on trails B). Nevertheless, over time the patients had nearly identical mean scores on each of the four subtests, which make the negative results in this population important.

In contrast to our earlier study most of the patients in this study were women and younger (mean age in the earlier study, 59.4 years; range, 22-86 years). These distinctions are important in view of the higher incidence of preexisting organic brain syndromes (primarily dementia) in older men (7). People with compromised cerebral function are more susceptible to delirium from further biological or psychological stress (8). The cognitive impairment found in patients in the earlier study may have been secondary to preexisting impairment or to an unmasking of subclinical impairment by chemotherapy. In addition, ectopic production of parathormone or vasopressin is known to occur in tumors, particularly lung cancers. These substances can produce delirium (9). Because 20% of the patients in the previous study had lung cancer, these hormones may have played a role in the higher occurrence of impairment found in that study.

The present study does not cast any doubt on the high occurrence of cognitive impairment in cancer patients nor on the fact that chemotherapy can cause cognitive impairment (3, 10). This study does suggest that factors other than chemotherapy are important in

causing cognitive impairment in cancer patients and that serial, rather than random, cognitive testing should be done to further elucidate these factors. Ideally, this testing should be done on patients who have the same cell type, stage and site of the disease, treatment, and premorbid cognitive status. In most cancer treatment centers stratifying a population to this extent will make it difficult to identify an adequate number of subjects. However, the multiinstitution cancer groups offer an opportunity to study the important problem of cognitive impairment in cancer patients in a controlled manner. Several studies of this type are currently being conducted in Cancer and Leukemia Group B, one of the multicenter study groups.

Strategy for the Study of Patients at High Risk for Tardive Dyskinesia

BY JOHN KANE, M.D., FREDERIC A. STRUVE, PH.D., PAUL WEINHOLD, PH.D., AND MARGARET WOERNER, PH.D

Despite a considerable increase in research that is relevant to tardive dyskinesia, our understanding of etiological factors of the disorder remains limited. The epidemiologic data implicating neuroleptics is quite convincing; however, possible risk factors relating to drug history variables are still difficult to identify (1).

Age and sex have frequently been implicated in the development of tardive dyskinesia—older female patients have been shown in several retrospective analyses (2-4) to have increased risk. Surprisingly, dosage and length of neuroleptic exposure have been inconsistently related to the risk of tardive dyskinesia development (5). It may be that the lack of evidence for such intuitive relationships is merely a methodological problem given the difficulties involved in retrospective data analyses, particularly in dating the onset of the syndrome, and given the complexities of drug metabolism. An alternative hypothesis is that individual vulnerability or sensitivity may be the most important single factor in producing high risk.

Our previous work (6) suggested that electroencephalographic abnormalities, particularly the B-mitten pattern, may indicate increased risk for tardive dyskinesia. The B-mitten pattern, which can be detected only during moderately deep sleep, consists of a sharp transient wave (often formed by the last wave of a frontal spindle) followed by a higher voltage slow wave; the resulting complex resembles the thumb and hand of a mitten. These signals occur over the bilateral fronto-parietal region. The B-mitten pattern is rare among normal subjects, occurs primarily among psychiatric patients, and does not appear to be caused by neuroleptic medication because it also occurs in patients not receiving neuroleptics.

In order to address the problem of determining a patient's risk for developing tardive dyskinesia, we identified and studied a group of patients who demonstrated a high risk for the development of the syndrome.

Method

During a 3-year period we reviewed 99 consecutive case histories of patients with presumptive tardive dyskinesia and identified 7 patients who satisfied our definition of high risk. We arbitrarily defined a high-

TABLE 1
Characteristics and Treatment Data for 7 Patients at High Risk for Tardive Dyskinesia

Patient	Age (years)	RDC Diagnosis	Drug Exposure (months)	Predominant Drug Class	Maximum Dose[a] (mg/day)	EEG Evaluation[b]	Tardive Dyskinesia Data	
							Severity	Follow-Up
1[c]	31	Bipolar II	9.0	Butyrophenone	1000	Normal (drug free); severe generalized and diffuse paroxysmal slowing (lithium)	Mild	Persistent after 15 months
2	15	Major depressive disorder, schizotypal features	7.0	Piperazine	2250	B-mitten dysrhythmia	Moderate	Remitted after 2 months
3	20	Other psychiatric disorder	5.5	Piperazine	80	B-mitten dysrhythmia	Severe, functionally impaired	Persistent for 2 years; neuroleptics withdrawn for 3 months
4	28	Other psychiatric disorder	4.0	Aliphatic	1200	Anterior brady-rhythmia	Moderate	Persistent after 9 months
5	59	Bipolar I	8.0	Piperazine	300	Normal[d]; no sleep recording	Moderately severe, functionally impaired	Persistent for 16 months; neuroleptics withdrawn for 10 months
6	47	Major depressive disorder, alcoholism	9.0	Piperazine	700	B-mitten dysrhythmia	Mild	Persistent after 6 months
7	29	Manic disorder	8.2	Butyrophenone	200	B-mitten dysrhythmia	Mild	Remitted after 1 month

[a]Maximum daily dose was received for a minimum of 1 month; doses in chlorpromazine equivalents.
[b]Evaluations made blind to tardive dyskinesia diagnosis.
[c]Only female patient.
[d]May be false negative for B-mitten dysrhythmia.

risk patient as anyone who developed presumptive tardive dyskinesia after less than 1-year cumulative lifetime exposure to neuroleptics.

Although no established criteria for the diagnosis of tardive dyskinesia have been developed, these patients had definite symptoms of at least mildly severe presumptive dyskinesias and several had moderate to severe symptoms. The diagnoses were made on a longitudinal rather than cross-sectional basis, and they were confirmed on several occasions by different examiners, including a neurologist. Two patients had dyskinesias of such severity that they were functionally impaired.

Results and Discussion

The characteristics of these patients are presented in table 1. Several findings should be noted: the patients' mean age was 33 years, 6 of the 7 patients were men, none met the Research Diagnostic Criteria (7) for schizophrenia, 6 of the 7 patients received predominantly high potency neuroleptics, and 4 patients received a maximum dosage for at least 1 month that was less than 700 mg/day of chlorpromazine equivalents.

The dyskinesias of 2 patients were reversed within 2 months after discontinuation of drugs; therefore, these patients might be considered in a different category. It would be difficult to consider these patients as having withdrawal dyskinesias because their dyskinesias emerged without reduction in or discontinuation of neuroleptic dosage. It is impossible to determine whether or not these patients would have developed persistent dyskinesias had their neuroleptics not been withdrawn following early signs of the syndrome. It is striking, however, that 4 of these patients have continued to manifest involuntary movements for at least 6 months following drug discontinuation; in three patients the movements continued to be at least of moderate severity, suggesting that these patients had considerable vulnerability to the disorder.

The most severely impaired patient received very low doses of neuroleptics, which suggests he was extremely vulnerable. He may have had some form of minimal brain dysfunction as a child; when he was 12 years old he had a brief exposure to chlorpromazine, but he had no history of psychostimulant exposure. It is conceivable that this history played a role in his apparent sensitivity to tardive dyskinesia.

EEG evaluations were made without any knowledge of a tardive dyskinesia diagnosis; 5 patients showed an abnormal recording and 4 patients had the B-mitten dysrhythmia (see table 1). The one patient who had no evidence of EEG abnormality had shown evidence of cognitive deterioration without gross neurological abnormalities. This suggests some degree of CNS dysfunction before the development of involuntary movements.

Possibly some degree of preexisting CNS dysrhythmia predisposes individuals to develop tardive dyskinesia. It is also noted that affective illness appears predominant in these patients. Although patients with all diagnoses are susceptible to dyskinesias, two anecdotal reports (8, 9) suggest that patients with affective illness may be at greater risk. The previously reported association of the B-mitten pattern with affective dysregulation is also of interest (10).

Two of these patients were 15 and 20 years of age. Because of their young age it is possible that they were exposed to neuroleptic medication in utero resulting in their unusual vulnerability. We questioned both patients' mothers, but we were unable to establish a history of neuroleptic use for antipsychotic purposes. However, antiemetic administration is difficult to rule out with certainty.

It is impossible to draw conclusions from this report except to suggest that persistent dyskinesias are not always tardive (that is, occurring late in exposure to neuroleptics) and that some patients appear exquisitely sensitive to this drug effect. The patients in this study may represent one subgroup of patients who develop tardive dyskinesia, and therefore, generalizations about the risk factors in this group cannot be made. Our findings are reported here for heuristic purposes; we are in the process of collecting data from a larger group of patients. We feel, however, that caution should be used when considering neuroleptics for conditions other than schizophrenia.

Tardive Tourette Syndrome in an Autistic Patient After Long-Term Neuroleptic Administration

BY STEPHEN M. STAHL, M.D., PH.D.

Gilles de la Tourette syndrome is a hyperkinetic movement disorder of unknown cause with onset during childhood and characterized by multiple chronic motor and vocal tics (1). Tourette syndrome patients may also exhibit some rather remarkable language and behavior disorders such as coprolalia, echolalia, copropraxia, echopraxia, and compulsive, organized stereotypies such as touching, kissing, and jumping (1, 2).

A number of recent investigations point to a genetic and biological basis for idiopathic Tourette syndrome (3). Pharmacologic observations suggest that idiopathic Tourette syndrome may be characterized by a relative imbalance between striatal dopamine and acetylcholine with dopaminergic hyperactivity and cholinergic underactivity (4, 5). Tourette syndrome symptoms are exacerbated by dopamine agonists (such as amphetamine, methylphenidate, and L-dopa), relieved by dopamine receptor blockers (i.e., neuroleptics). Evidence for the role of a dopamine-acetylcholine imbalance in idiopathic Tourette syndrome is strengthened by observations that dopamine agonists can induce motor and vocal tics as well as stereotypies in patients who do not have Tourette syndrome (6). Furthermore,

it now appears that Tourette syndrome can be induced in patients by long-term neuroleptic therapy; in that respect Tourette syndrome is analogous to tardive dyskinesia (7). In the case report below we describe a residual autistic adult who had an onset of Tourette syndrome after long-term neuroleptic administration.

Case Report

Mr. A, a 28-year-old man, came for an evaluation because he had uncontrollable motor and vocal tics that had lasted 2 years. He was the product of a full-term pregnancy with normal labor and low forceps delivery. Mr. A's growth and developmental milestones were normal up to 14 months of age, when his parents noted he made bizarre sounds and had paucity of speech and poor understanding of spoken language. By age 3 he avoided eye contact; developed stereotyped hand movements, flapping, and rocking; was fascinated by spinning objects; and would stand at the sink and run water through a funnel endlessly. When he was 5 years old, he could communicate simple thoughts with single words or short phrases in a staccato speech with pronomial reversal. He attended public school for 3 years, where his bizarre behavior, delayed language skills, and functional retardation were noted; his IQ was in the range of 45–55. At age 11 he entered a program for the mentally retarded. An examination at this time by numerous consultants revealed normal neurological findings with no abnormal movements except for the rocking motions of his trunk. An EEG revealed mild left temporal slowing. At age 13, he entered a state hospital because he failed to improve. He received neuroleptics (200 mg/day of chlorpromazine or thioridazine) continuously over the next 13 years; he also received diazepam or phenobarbitol on rare occasions for sleeplessness or agitation.

When Mr. A was 26 years old, he was returned home to his parents, and they requested that the thioridazine be discontinued. Approximately 2 to 4 weeks after the gradual tapering of thioridazine, he developed facial tics, grunting, and involuntary limb movements. A neurological evaluation at this time revealed the presence of frequent bilateral lower facial tics, sniffing, grunting, barking, occasional whispered coprolalia, and tic-like movements of the neck, torso, abdominal muscles, and diaphragm, the latter especially accompanying vocalizations. An EEG again showed Mr. A had left temporal slowing. A CT scan of the brain was normal. Phenytoin and primidone were prescribed for Mr. A, but he did not improve. Over the next 2 years his movement disorder persisted but was nonprogressive. Mr. A's tics were exacerbated by agitation or stress and relieved by sedation; he had little or no voluntary control over them.

A neurological examination of Mr. A at the age of 28 yielded findings that were unchanged from earlier neurological examinations. A comprehensive review of Mr. A's medical records, as well as psychological, speech and language, and psychiatric assessments showed that he met the *DSM-III* criteria for infantile autism, residual state. A brief trial of haloperidol completely suppressed his motor and vocal tics; d-amphetamine severely exacerbated these symptoms. Mr. A received an intravenous infusion of physostigmine salicylate, 4 mg over 60 minutes, after pretreatment with 6.25 mg of propantheline bromide i.v. An observer who was blind to Mr. A's treatment studied videotapes taken of Mr. A during this time and counted the number of tics he had; the observer noted that Mr. A's tics were completely suppressed for 6 hours starting 30 minutes after the infusion.

Discussion

Although the motor and vocal tics present in this patient are identical to those of idiopathic Tourette syndrome, several features of his case clearly distinguish it from classical Tourette syndrome. First, according to the criteria of *DSM-III* and Shapiro and associates (2) the age of onset (26 years) was atypically delayed. Second, the movement disorder was superimposed on the syndrome of residual infantile autism. Also, the onset of the syndrome in Mr. A occurred shortly after discontinuation of chronic neuroleptic treatment. Furthermore, Mr. A's tics were under no obvious control and fluctuated relatively little over time.

To our knowledge, this represents the first reported case of concurrent Tourette syndrome and infantile autism. Caine and associates (8) reported a patient with Tourette syndrome who was treated for a long time with haloperidol and who developed psychosis upon withdrawal of the medication. Klawans and associates (7) reported a patient with schizophrenia who was treated for a long time with chlorpromazine and who developed Tourette syndrome upon withdrawal of medication. Our patient thus appears to be the second reported case in which the manifestation of neuroleptic withdrawal dyskinesia has taken the form of Tourette syndrome. We have coined the term "tardive Tourette syndrome" to distinguish this particular syndrome from classical Tourette syndrome. We have also coined the term "toxic Tourette syndrome" to designate Tourette syndrome induced by dopamine agonists. Thus, we can now distinguish two unique forms of Tourette syndrome from classical Tourette syndrome, namely tardive Tourette syndrome and toxic Tourette syndrome.

Our observations thus have several important implications. 1) Tardive dyskinesia can take the form of Tourette syndrome as well as classical oro-buccal-lingual dyskinesias. 2) The pharmacology of tardive Tourette syndrome is identical to that of both tardive dyskinesia and classical Tourette syndrome, namely, exacerbation by d-amphetamine and amelioration by haloperidol and by physostigmine. 3) The pathophysiology of both Tourette syndrome and tardive dyskinesia can be characterized by dopamine-acetylcholine imbalance, with relative dopamine excess and relative acetylcholine deficiency. 4) The etiopathologies of tardive dyskinesia and Tourette syndrome might also be linked, so that data and hypotheses relevant to one syndrome may be applicable, by analogy, to the other. Thus, supersensitivity of postsynaptic dopamine receptors, possibly the cause of tardive dyskinesia (9), may also be important in Tourette syndrome. 5) Finally, clinicians should be aware of the possibility that the emergence of Tourette syndrome in a given patient might be secondary to withdrawal of neuroleptics and

that patients treated with chronic neuroleptics may be at risk for tardive Tourette syndrome as well as tardive dyskinesia.

Psychogenic Oligodipsia with Hypernatremia in a Psychotic Patient

BY IRVING M. NADLER, PH.D., AND MAVIDI K. HARIPRASAD, M.B.B.S.

Hypernatremia often causes lethargy, confusion, stupor, or coma and occasionally causes muscle irritability and convulsions. The common causes of hypernatremia include central nervous system lesions of the hypothalamus or supraoptico-hypophysial tracts, circumstances in which the patient has been unable to freely obtain water (this includes impairment of sensorium), or nephrogenic diabetes insipidus (1).

We report below a case of psychogenic oligodipsia with hypernatremia in which a psychotic patient drastically reduced his liquid intake apparently in response to psychological conflicts. The diametrically opposite syndrome, psychogenic polydipsia with hyponatremia, is well documented in psychotic patients (2, 3). As a result, it has been suggested that medical staffs monitor serum sodium levels routinely in psychotic patients when polydipsia is suspected (3, 4). An increase in gross neurobehavioral signs, such as agitation or confusion, or an increase in psychotic symptoms may reflect polydipsia (2).

The patient in this case was discovered when routine electrolytes were taken during his stay on a psychiatric unit; the tests indicated the patient had a serum sodium level of 178 mEq/liter (normal range, 135-145 mEq/liter). Surprisingly, the patient was alert and ambulatory, showing none of the above mentioned symptoms of hypernatremia. He refused to drink water and was transferred to the intensive care unit where intravenous fluids were initiated.

Case Report

Mr. A, a 58-year-old man, had the first of several psychiatric admissions 18 years ago; he has been continuously hospitalized for 8 years. The treatment team diagnosed him as having schizophrenia, chronic undifferentiated type. Mr. A had been treated for neurosyphilis, but subsequently he had a nonreactive serum and cerebral spinal fluid VDRL. There were no neurological stigmata of syphilis; tardive dyskinesia was the only neurological abnormality noted.

Mr. A had the appearance of a regressed psychiatric patient. He had difficulty communicating, rambling speech, and a short attention span; he was agitated, negative, and manneristic. Immediately before the discovery of Mr. A's dehydration it was noted that his usual level of agitation and hostility increased. No hallucinations or delusions were evident. He was taking 50 mg q.i.d. of hydroxyzine hydrochloride; thioridazine had been discontinued during the previous month.

The physical findings that were relevant in Mr. A's case included minimal dryness of the tongue and skin and normal blood pressure. He reported an absence of thirst. After three days of parenteral fluid therapy, his serum sodium level decreased from 178 to 145 mEq/liter. During this period, as Mr. A went from severe to mild hypernatremia, several urine osmolality determinations exceeded 600 mosmol/kg. These osmolality data reflect adequacy of the urine-concentrating mechanism and indicate normal secretion of antidiuretic hormone, normal kidney functioning, and the absence of any

adverse drug effects. Thus, central nervous system lesions or nephrogenic diabetes insipidus were excluded as causes of the hypernatremia (5). Also, had he wished to do so, Mr. A was able to freely obtain water. No predisposing medical illness was found to account for his decrease in fluid intake, but there were obvious psychological reasons for his reluctance to take fluids.

Mr. A's self-induced dehydration was associated with a recurring psychological conflict. The first manifestation of this conflict had occurred 30 years earlier, when Mr. A had a hemorrhoidectomy. At that time he became preoccupied with bowel movements and accidentally defecated while riding in a bus. He was embarrassed and subsequently spent inordinate amounts of time in the bathroom for fear of fecal incontinence. At the peak of his disturbance, he remained in the bathroom for 2 years. He slept there, and his mother and wife brought him food. Mr. A's bizarre behavior persisted for more than a decade before his family brought him in for psychiatric treatment. In recent years Mr. A was spending much less time in the bathroom.

The conflict reemerged in a new form when Mr. A developed benign prostatic hypertrophy with urinary incontinence. The staff frequently found it necessary to ask him to change his clothing and to shower, and again he was quite embarrassed. His fear of urinary incontinence continued despite the fact that his control improved following prostatic surgery. He rushed to the bathroom to urinate, showered several times daily, and reduced his fluid intake. Even though he was severely dehydrated he reported an absence of thirst; he refused to drink anything except about two cups of coffee per day and ate dry cereal without adding any liquid. After the parenteral fluid therapy, Mr. A was eventually coaxed into drinking about two more cups of coffee per day. He still refused to drink any other liquid but willingly ate jello (seemingly unaware of its high water content). Thus, Mr. A's serum sodium ranged from 138–147 mEq/liter during the next six months.

Discussion

We have reported a case of severe hypernatremia in which a psychotic man drastically reduced his fluid intake. No medical conditions were found to account for his reduction of fluid intake, but it was associated with a recurring psychological conflict. Dehydration is a common problem in psychiatric patients who are stuporous (e.g., in catatonic states), but our patient was alert, ambulatory, and had no eating problems. To our knowledge this is the first reported case of psychogenic oligodipsia, a syndrome diametrically opposite to the frequently reported psychogenic polydipsia. Drinking is one of our most primitive drives, and indeed, only in a severely disturbed person could this powerful drive be thwarted. The prevalence of psychogenic oligodipsia is a matter of speculation. In view of the possibilities of morbidity and mortality associated with hypernatremia and hyponatremia (1), we suggest monitoring serum sodium levels in all psychotic patients to identify those patients who may have oligodipsia or polydipsia.

Misidentification of a City: Delimiting Criteria for Capgras Syndrome

BY MARIE INGRAM THOMPSON, M.D., KENNETH R. SILK, M.D., AND GERALD L. HOVER, PH.D.

In 1923 Capgras described a symptom of delusional misidentification wherein the patient believes that a familiar, emotionally charged other person has been replaced by a duplicate or double of that person (1). The patient appears to retain recognition of the significant other person's external appearance but then delusionally denies the other's identity, claiming the other person has been duplicated by an imposter. This misidentification classically occurs with a clear sensorium (2).

The Capgras delusion is usually limited to those persons closest to the patient (a spouse, child and/or parent). Often there is some explanation for the disappearance of the real person (kidnapped, imprisoned, murdered). The imposter is frequently endowed with persecutory, sexual, or hostile intentions toward the patient (3).

Attempts have been made to explain the Capgras syndrome from either psychodynamic or neurologic

perspectives. Psychodynamic theory states that Capgras is a mental mechanism wherein the patient is unable to repress intense ambivalence toward a love object (2, 4). The patient expresses this ambivalence in a psychotic manner, splitting the object representation into good and bad and concretizing the bad in the form of the imposter (2). Neurologic hypotheses have usually equated Capgras with prosopagnosia, i.e., the inability to recognize faces (5–7). It is postulated that an anatomic defect in striate and parastriate areas of the cortex, which may possibly involve portions of temporal, parietal, and/or occipital lobes, causes the nonrecognition.

The case presented here is an unusual variant of Capgras syndrome. The patient maintained that there were at least eight duplicates of his wife and children, each duplicate living in a separate duplicate city with a double of the patient. A literature review (3, 8, 9) failed to uncover a similar case, although Forth and Theofilopolous (10) recently described a case wherein inanimate objects were replaced by duplicates.

Case Report

Mr. A, a 32-year-old unemployed man, was admitted with a diagnosis of schizophrenia (*DSM-III*). He was legally separated from his wife and four children and lived alone. His parents had been divorced when he was 17 years old. He had one younger sister.

At 20 years of age, he joined the service. After 7 months Mr. A was discharged with the diagnosis of schizophrenia, paranoid type. He had repeatedly experienced auditory hallucinations commenting on his activities. He believed his feelings and thoughts were controlled by the same force that governed the voices. In the decade since his service discharge Mr. A had been hospitalized approximately 20 times for periods of 1 to 3 months. Auditory hallucinations and exacerbation of paranoid ideation with accompanying delusions of control were the usual precipitants of his hospitalizations. Mr. A improved markedly after he began receiving antipsychotic medication; however, he would discontinue the medication when he was discharged from the hospital.

Despite remission of other symptoms, Mr. A had a persistent delusional misidentification that began with the onset of his psychosis. After returning home from the service he believed he had arrived at a city that appeared to be an exact replica of his hometown, but he knew it was an "imposter-city." He first thought the imposter-city was located in Russia, but later he acknowledged that some imposter-cities were in the United States. He stated that there were eight imposter-cities and that he had spent the last 8 years wandering between them without finding the real one. (His wife reported that he always returned to his hometown between hospitalizations.) Each imposter-city had duplicates of his family members. He knew they were imposters because they did not "feel" like the real people to him. He believed that in his real hometown his real family was deceived by an imposter of himself who replaced him in his absence.

Two years ago Mr. A claimed he found his way back to the real city and rediscovered his wife. He cannot explain what happened to the imposter of himself or to the other imposter-cities and families. He says that they must exist somewhere. These ideas persist despite continued exacerbations and remissions of his illness over the last 2 years.

Mr. A had no history of substance abuse, head trauma, or loss of consciousness. His medical history was negative, and his family history was negative for psychiatric or neurologic disorders. The findings from a neurologic consultation, including an EEG and CT scan, were essentially within normal limits. His IQ was 111 (verbal, 121; performance, 97). Neuropsychological testing administered after Mr. A felt that he was in his real home revealed he had difficulty with tasks requiring figure drawing and picture sequencing. He was able to retain visual images.

Discussion

The multiplicity of doubles, as well as the extension of doubles to inanimate objects (cities), makes this case an unusual variant of Capgras. However, the case is typical of Capgras because Mr. A recognized who the people and city were supposed to be but delusionally misidentified them as being clever copies of the actual objects. Therefore, despite Mr. A's perceptual difficulties on neuropsychological testing, his pathology lay not in an error of recognition but in the formation of a delusion.

This recognition of who the object is supposed to be helps to delimit Capgras from neurologic disorders. Prosopagnosia, the nonrecognition of faces, and the broader concept of agnosia in general involve loss of the ability to recognize the typography (i.e., the surface physical characteristics) of a face or object and are true *an*identifications. Similarly, patients may suffer from anomia, the loss of ability to name a familiar object, or from aphasias in general. These disorders, singly or in combination, may be accompanied by random confabulation.

The above disorders stand in clear contrast to the psychosis seen in Capgras. The Capgras patient recognizes the typography of the object and knows who or what it is supposed to be. The patient, however, denies the object's reality and then delusionally misidentifies it as an imposter or duplicate.

We suggest that the pathology of Capgras lies not in a perceptual error but in the patient's disordered response to a clearly recognized object. Limiting the diagnosis of Capgras syndrome to cases that involve the elements of 1) recognition, 2) naming, 3) denial, and 4) delusional misidentification would distinguish it as a functional disorder, clearly differentiated from the neurological problems of naming and perception.

Tardive Dyskinesia and Body Weight

BY JAMES M. SMITH, PH.D., DANIEL D. DUNN, M.A., AND MARY P. BURKE, M.A.

Although a considerable amount of research on the manifestations and treatment of tardive dyskinesia has been conducted during the past two decades, it is only recently that systematic attention has been given to other deficits that may be associated with this disorder (1, 2). Among these deficits, several authors have noted a weight loss in some patients with tardive dyskinesia. Gardos and associates (3) reported significant negative correlations between tardive dyskinesia ratings and body weight in two patients studied longitudinally. In both patients the highest correlations with weight loss involved neck and trunk movements, suggesting that these movements led to increased energy expenditure with an almost immediate weight loss. Furthermore, it was their visual impression that there was a preponderance of thin tardive dyskinetic patients. Sovner (4) also indicated that weight loss secondary to the constant movement of tardive dyskinesia may be one of the complications of the disorder. Weight loss associated with Huntington's chorea has been explained similarly (5).

Even though these authors suggest that weight loss is secondary to the constant movement, there is also the possibility that a more central mechanism may be involved. Animal studies have implicated brain catecholamines in the regulation of food and water intake, and some clinical data suggest the involvement of dopaminergic systems in particular. Rosenberg and associates (6) reported that Parkinson's disease, which involves a diminution of dopaminergic activity, is occasionally associated with an abnormally increased sensation of hunger and an insatiable appetite. In addition neuroleptic drugs, which decrease dopaminergic activity, frequently result in weight gain (7). On the other hand, drugs that increase dopaminergic activity, e.g., dextroamphetamine, have anorectic effects with subsequent weight loss without appreciable increases in movement. One hypothesis is that tardive dyskinesia results from a neuroleptic-induced dopaminergic hyperactivity in the nigrostriatal tract, therefore, it is conceivable that a parallel hyperactivity may be evidenced in other dopamine tracts in the brain as well. One indication of this would be the development of anorexia and subsequent weight loss. This weight loss would be typical of tardive dyskinesia in its myriad forms and not merely secondary to severe gross body movements.

To our knowledge there has been no large-scale study of this topic. In addition to being of direct clinical interest, the demonstration of dopaminergic parallelism would lend indirect support to the notion that there may be a similar parallelism leading to a supersensitivity psychosis (2). In order to study the relationship between weight loss and tardive dyskinesia, we examined patient data from a previous study on tardive dyskinesia (8).

Method and Results

In a study to determine the prevalence of tardive dyskinesia among inpatients at the Harlem Valley Psychiatric Center, Smith and associates (8) obtained informed consent from 377 of the center's inpatients. Two examiners rated these patients on the Abnormal Involuntary Movement Scale (AIMS), which was designed by the National Institute of Mental Health to measure the presence and severity of abnormal movements in seven body areas. Of the 377 patients rated, 293 had a primary or secondary diagnosis of schizophrenia at some time during their hospitalization; 30% of these 293 patients had at least moderately severe

[b]Weight data recorded at time of AIMS evaluation.

symptoms of tardive dyskinesia. Details on AIMS and the examination procedures employed were reported in that study.

Our follow-up study was conducted 2 years later. Of the 293 patients in the original sample who were diagnosed as suffering from schizophrenia, 168 patients remained as inpatients, 97 patients were discharged, 20 patients died, and 8 patients were transferred to other institutions. By means of a retrospective chart review of the inpatients and discharged patients, we obtained the weight of each patient at the time nearest the date of the patient's AIMS examination. This information was available for all of the 168 current inpatients and for 85 of the 97 discharged patients, yielding a total sample of 253 patients (129 men and 124 women). Predicted weights were computed for each of these patients based on sex, age, and height according to the regression equations presented by the National Center for Health Statistics (9). In addition, for the sample of 168 inpatients (87 men and 81 women) current weights were obtained, that is, the patient's weight nearest the time of this follow-up. Finally, weight difference scores (raw scores as well as percent difference scores) were computed. We calculated the differences between 1) weight at the time of the AIMS evaluation and predicted weight for all 253 patients, 2) current weight and weight at the time of the AIMS evaluation for the 168 inpatients, and 3) current weight and predicted weight for the 168 inpatients.

Because age and sex have been shown to be related to dyskinesia, separate two-way analyses of variance (dyskinesia by age group) were conducted for each of the sexes. The age variable was dichotomized at age 60 (<60, ≥ 60) and the presence of dyskinesia was defined as an average rating of 2.5 or higher in any one or more of the AIMS body symptom areas. The latter criterion has been used previously (10). These analyses were performed on the AIMS weight of the patients, their predicted weights, current weights, and the three weight difference scores (both as raw scores and percent difference scores). Some of these data are presented in table 1. Although the mean differences for the younger group are in the predicted direction, in none of these analyses was dyskinesia or the interaction of dyskinesia with age statistically significant.

Because the analyses of variance took account only of the presence or absence of dyskinesia, it also seemed useful to determine whether there was a relationship between severity of dyskinesia and weight. We obtained this information by computing the correlations between AIMS item scores and AIMS weight, current weight, predicted weight, and the three difference scores (both raw scores and percent difference scores). In addition to the AIMS item scores AIMS total scores (sum of the first seven items), AIMS face scores (sum of the first four items), and AIMS extremity/trunk scores (sum of items 5, 6, and 7) were included in the correlational analyses. The latter two sub-

scores (AIMS face score and AIMS extremity/trunk score) were utilized to determine whether a weight effect might be associated more with severity of gross body movements. To eliminate age and sex as confounding factors in the correlational analyses, separate correlation matrices were computed for younger and older men and younger and older women; the age groups were dichotomized at age 60 as in the previous analyses. There were few statistically significant relationships, and because the relationships presented no consistent pattern they could easily be attributed to sampling fluctuations. Of particular interest is the fact that the AIMS extremity/trunk scores did not show higher correlations with weight than did AIMS face scores.

Discussion

These results indicate that tardive dyskinesia is not associated with a general and characteristic weight loss. In interpreting this finding one should bear in mind several factors. First, this study was conducted in an inpatient setting where weight is regularly monitored. Presumably, if a patient varied appreciably from his normal weight, attempts would be made to correct this deviation and this would attenuate weight changes associated with tardive dyskinesia. Furthermore, in older patients it is easy to see how any weight change induced along with tardive dyskinesia could be obscured by the overriding effects of physical illness on weight. One would not, of course, expect this factor to apply to young patients to any great extent because young patients are not as likely to suffer from serious physical illness. Finally, this was a cross-sectional study, and no conclusions can be drawn about the weight changes that might be evident only at the time of the initial development of tardive dyskinesia and that might show some adaptation. In our sample, especially in the older patients, undoubtedly many developed tardive dyskinesia a number of years before the AIMS ratings.

These considerations notwithstanding, the results of this study demonstrate that there are no characteristic and persistent weight changes associated with tardive dyskinesia of sufficient magnitude to offset other factors that influence body weight. Although Gardos and associates (3) presented longitudinal data on two patients showing a relationship between the exacerbation of gross body movements and weight loss, the results of the present cross-sectional study indicate that weight loss is not typical, even in patients with severe movements. Several of the patients in the sample had severe gross body movements, yet they showed little or no weight loss. This finding also suggests that the weight loss in Huntington's chorea may not necessarily be secondary to the choreic movements, as is commonly assumed.

Antimanic Effect of Clonidine

BY ROLAND JOUVENT, YVES LECRUBIER, ALAIN J. PUECH, PIERRE SIMON, AND DANIEL WIDLÖCHER

The role of norepinephrine in affective disorders remains the subject of extensive discussion and research. We have undertaken a systematic investigation of the effects of central stimulating or blocking agents of noradrenergic receptors in this context (1, 2). We hypothesized that the use of a stimulant of α-adrenergic presynaptic receptors, which reduces the release of norepinephrine (3), might be effective in the treatment of manic states. We decided to explore clonidine because its central effects have received some support. For example, clonidine has sedative effects (4), a favorable effect on the withdrawal syndrome in drug dependence (5, 6), and the side effect of inducing a depressive syndrome when prescribed for hypertension (4).

Method

We studied the antimanic properties of clonidine in eight patients. Patients 1-5 were hospitalized in our department of psychiatry for the present episode, i.e., a typical manic episode with increased mood level, flight of thoughts, increased motor and verbal activity, but not schizophrenic symptoms. Patients 7 and 8 were hypomanic when they came to the outpatient department; they had been hypomanic for at least 8 days when we prescribed clonidine. They continued to be treated as outpatients. Patients 1-5 and 7 and 8 were bipolar, i.e., had previous occurrences of depression. Patient 6, the only unipolar patient, was a long-term inpatient hospitalized for chronic mania, which had not notably improved by the use of neuroleptics.

We progressively increased each patient's dose from $1^1/_2$ to 3 tablets of clonidine per day (1 tablet = 0.15 mg) within 3 days according to tolerance and efficacy. At night all patients received diazepam (10 mg) as a hypnotic, except for patient 7, who received chlorpromazine (25 mg). Although patient 8 had relapsed under lithium treatment, this treatment was maintained (blood level, 0.5-0.6 mEq/liter). We decided to add droperidol in case of insufficient action of clonidine, and this possibility was a means of indirectly evaluating clonidine efficiency.

Inpatients were seen twice daily by a psychiatrist and were rated once daily, always at the same hour (9 a.m.-10 a.m.), by another independent psychiatrist (R.J.) who used the mania rating scale of Bech and associates (7), an 11-item scale on which each item is scored on a 5-point scale (range=0-44). The symptoms assessed concerned motor activity, verbal activity, flight of thoughts, noise level, hostility, mood level, self esteem, contact, sleep, sexual activity, and work.

Outpatients were evaluated under the same conditions by the same rater but at 3-day intervals. All patients were rated before treatment began and again at days 3 and 6 of treatment.

Results

We observed a strong global improvement in three of the eight patients (patients 1, 5, and 8) and partial improvement in three others (patient 4, who improved in all symptoms, and patients 6 and 7, who improved in mood and motor agitation only). Only two patients required administration of droperidol: patient 1 on only the first day of treatment and patient 2, who did not respond to clonidine or to clonidine plus oral droperidol and required droperidol by intramuscular injections. The fact that for 6 patients out of 8, their psychiatrists did not find it necessary to add droperidol is further but indirect argument in favor of clonidine's antimanic effect.

All patients except patients 2 and 4 registered a notable reduction in sleep disturbance. The fact that efficacy was slight until day 3 is probably due in part to the slow increase in doses. Although not indicated in table 1, better results at day 3 were obtained when tolerance permitted a rapid increase to 0.45 mg (3 tablets) of clonidine, which seems to be an effective dose. The age, sex, diagnosis, associated treatments, and scores on the Bech scale for all patients are given in table 1. Clonidine treatment was discontinued on day 2 for patient 3 because of arterial hypotension; all other patients exhibited only slight hypotension (10-20 mm Hg) and no clinical expression during the course of clonidine treatment. Patients 5 and 8 exhibited a mood inversion (depression) necessitating the discontinuation of clonidine after 1 week of treatment; patient 8's mood spontaneously returned to normal, but for patient 5 the initiation of antidepressant treatment was necessary.

Comment

It is too early to ascertain the therapeutic usefulness of clonidine as a common treatment of manic states. Our clinical impression is that clonidine has an authen-

TABLE 1
Demographic, Diagnostic, and Treatment Data for Eight Manic Patients Taking Clonidine[a]

Patient[b]	Age (years)	Sex	Diagnosis	Associated Treatments (mg/day)	Bech Scale Scores[c] Day 0	Day 3	Day 6
1	28	M	Acute mania	Droperidol, 50 1st day only; diazepam, 10	25	12	3
2	40	F	Acute mania	Droperidol, 150; diazepam, 10	30	31	—[d]
3	67	M	Acute mania	Diazepam, 10	23	—[e]	—
4	33	M	Acute hypomania	Diazepam, 10	19	19	6
5	66	F	Acute mania	Diazepam, 10	32	28	4[f]
6	58	M	Chronic mania	Diazepam, 10	24	16	11
7	44	M	Acute hypomania	Chlorpromazine, 25	19	16	6
8	68	F	Acute hypomania	Lithium carbonate, 750; diazepam, 10	16	10	4[f]
Mean (±SD)	50.5±16.2				23.5±5.5	18.9±7.9	5.7±2.9

[a]Maximum dose=0.45 mg/day.
[b]Patients 1–6 were inpatients; patients 7 and 8 were outpatients.
[c]Range=0–44, where 0=normothymic state and 44=maximal intensity of manic state; a score of approximately 10–20 indicates hypomanic state.
[d]Clonidine discontinued on day 4 for inefficacy.
[e]Clonidine discontinued on day 2 for severe hypotension.
[f]Inversion of mood.

tic antimanic, as opposed to purely sedative, effect. It is now recognized that α-adrenergic presynaptic stimulants such as clonidine and β-adrenergic blockers such as propranolol are able to reduce noradrenergic function (3). A relationship between this property and the effectiveness of these drugs in treating mania is strongly suggested by our results and those showing the efficiency of β-blockers in mania (8). All these data indicate the need for further investigation.

LETTERS TO THE EDITOR

This section contains reactions to Journal *articles, statements of opinion, brief research findings or ideas, short case descriptions, requests for information, etc. Letters should be submitted in duplicate to the Editor, who makes all decisions regarding publication. Letters must be typed double spaced throughout and should not contain more than 500 words and 5 pertinent references. Criticisms of published articles will automatically be sent to the author(s) for response. Letters will be edited for clarity and conformance with* Journal *style. We regret that we cannot inform writers of the disposition of letters or return those which are not printed.*

More on Medical Responsibility

SIR: I wish to respond briefly to Dr. Frederick J. Stoddard's comment (September 1980 issue) on my article "'Medical Responsibility' in Institutional Settings." It seems to me that Dr. Stoddard and I agree about the problem but disagree about the direction in which the resolution lies. His is the more optimistic view. All of his options rely on significant increases in resources. I hope he is correct, but I see little on the horizon to suggest either that the monies needed to support better care in institutions will be forthcoming or that enough doctors will go into psychiatry or enough psychiatrists will want to work in institutional settings.

The new APA guidelines about which Dr. Stoddard speaks are commendable. However, they do not define adequacy of supervisory contact. Further, the guidelines are not official policy; they may "be adapted to local customs and practice." The billing guidelines are an improvement. Unfortunately they will further erode the already collapsing funding base of many institutions.

High principles that cannot realistically be implemented are merely rhetoric. Many psychiatrists in institutional settings cannot even follow the current guidelines—indeed, the logistics of the system make it impossible. Why then should we feel that publishing new and stricter guidelines will be more than rhetoric? I am not particularly interested in writing a new code of ethics per se; I wish to use such writing to design an improved, if imperfect, delivery system.

It is not correct to characterize my approach as a retreat from responsibility. The retreat occurred long ago when the practices I mentioned in my paper became de facto standards of institutional procedure. Dr. Stoddard and I both advocate advances; he advocates a further advance than I do, but I believe mine has a greater likelihood of being attained.

Memphis, Tenn.

Galactorrhea and the Factors Behind Symptom Production

SIR: Richard M. Zeitner, Ph.D., and associates' case report "Pharmacogenic and Psychogenic Aspects of Galactorrhea" (January 1980 issue) is an example of the difficult beginning attempts we make to understand the interaction of pharmacological, endocrinological, and psychological factors in symptom production. I would like to add these comments to the complex interaction that may have been involved in this case.

Peptide hormones, such as prolactin, are often involved in the regulation of several organs. These different organs may be involved in a single physiological effect with the apparent adaptive advantage that effects on the different organs may be correlated in a "foolproof way" (1).

The brain is included in these organs. Thus, a one-way model of brain-hormone interaction is no longer tenable since hormones affect the brain and behavior. Such effects are currently the subject of much intense investigation (2). An awareness of this mutual interaction may help us to understand and more appropriately treat our patients and, in turn, may help us better understand these interactions.

Prolactin, in addition to playing an important role in mammillary development, also plays an important role in regulating mammalian maternal behavior (3, 4). However, prolactin may have several different functions in different species; thus the specific relevance of the above to humans is questionable. Yet, elevated prolactin levels have been associated in both men and women with decreased sexual desire and sexual dysfunction that may be relevant to maternal behavior (5).

The elevated prolactin levels of the patient described by Dr. Zeitner and associates may have led to an intensification of her maternal desires and conflicts, and added to her feelings of uselessness after the loss of her children. This might occur as a result of either a direct effect of prolactin on the brain or the indirect effect of its induced breast changes on physiological functions and the patient's perceptions of herself. Thus, by the mechanisms noted above, decreasing the patient's medication, as the authors did, would not only be directly helpful in decreasing the patient's obvious symptom of galactorrhea, but might also help to decrease her maternal conflicts.

If elevated prolactin levels directly or indirectly intensify maternal conflicts in patients, decreasing prolactin levels by the use of a dopaminergic agonist such as bromocriptine might be helpful in less complicated cases.

The authors noted that since Ms. A's first psychotic episode she had had three exacerbations, each characterized by auditory hallucinations and preoccupations with "a child being hurt" and "someone desperately needing me." Did the specific content of these hallucinations begin only after neuroleptic treatment and elevation of the patient's prolactin level? Could these be attributed in part to elevated prolactin levels and thus be considered a side effect of her medication?

Iowa City, Ia.

Dr. Zeitner Replies

SIR: Dr. Cohen's speculations are intriguing and further accentuate our contention that the most comprehensive formulations of clinical phenomena occur when investigators make attempts to translate etiology and treatment strategies from one level of understanding to another (i.e., a translation of psychological events into the language of neuroendocrinology).

In regard to Dr. Cohen's final speculation, the hallucinations involving "a child being hurt" and "someone desperately needing me" occurred when Ms. A was on no medication at all. Nonetheless, Dr. Cohen's thoughts about the interdigitation of prolactin and Ms. A's maternal conflicts provide another useful perspective in considering this case.

Kansas City, Mo.

Prison Mental Health Programs in North Carolina

SIR: "The Violation of Psychiatric Standards of Care in Prisons" (May 1980 issue) by Edward Kaufman, M.D., was timely and challenging. Dr. Kaufman obviously has had personal experiences worthy of noting, especially by those who are unconcerned about the psychiatric care of prisoners. Regrettably, many of these prisoners are poor and black. The miscarriage of justice for some citizens begins before they are ever arrested, and continues during imprisonment and throughout their lives.

However, I have great concerns about some of the sweeping generalizations Dr. Kaufman made about all prison mental health programs, federal and state. I am particularly troubled by the statement that "the conditions in the 3 recently examined prison systems reflect the general situation in prisons everywhere in this country." Apparently, Dr. Kaufman is unfamiliar with the mental health facility of the Federal Bureau of Prisons in Butner, N.C., that has a physical structure equalled by few private institutions and that is certainly superior to the majority of antiquated buildings found at state mental hospitals. The Butner facility provides quality treatment with the opportunity for vocational, occupational, and recreational therapies. Similarly, the mental health programs in the North Carolina State Penal System have been raised to a new and respectable level by the hard work of a nationally known pioneer of correctional psychiatry, Charles E. Smith, M.D., of the University of North Carolina at Chapel Hill, and the staff of the Department of Psychiatry, Duke University Medical Center.

We believe that training institutions should be involved in the management of mental health programs in corrections and responsible for preparing professionals to meet the special needs of incarcerated patients, thus raising the standards of care. In fact, psychiatric residents and medical students from both of these universities are afforded supervised electives in the psychiatric care of inmates. Our students have given this experience astonishingly high ratings.

It seems grossly unreasonable to have state mental hospital systems assume the added burden of caring for mentally ill inmates when most state mental hospitals cannot adequately care for their own patients. Moreover, penal mental health programs provide care for mentally disturbed inmates who are victims of the recent massive deinstitutionalization that occurred without sufficient planning. Penal institutions should develop autonomous comprehensive health care systems because the successful treatment of mental illness does not occur as an isolated phenomenon. Assuming inmates will return to prison once restored, they will require adequate follow-up care. Nothing can be more unsettling than the shuttling of chronically disturbed inmates between treatment facilities that may have discrepant treatment philosophies.

JAMES H. CARTER, M.D.
Durham, N.C.

Enuresis and Incontinence Occurring with Neuroleptics

SIR: In "Nocturnal Enuresis Caused by Psychotropic Drugs" (June 1980 issue) Ramakrishan S. Shenoy, M.D., further corroborated our clinical observation of urinary incontinence in patients receiving neuroleptics (1). Urinary incontinence as a side effect of phenothiazine and butyrophenone derivatives is more common than previously realized.

We reviewed this clinical phenomenon and its pathophysiological implications. Several additional facts need emphasis. Enuresis and/or daytime urinary incontinence occur with the following neuroleptics: chlorpromazine, thioridazine, chlorprothixene, thiothixene, fluphenazine, trifluoperazine, and haloperidol. Enuresis/urinary incontinence with neuroleptics appears to be an acute to subacute treatment-emergent symptom of drug administration occurring within hours or sporadically over the first several weeks regardless of the patient's previous genitourinary condition. This enuresis/urinary incontinence appears to diminish with continued neuroleptic administration or follows an on-off pattern when the drug is discontinued. Enuresis and urinary incontinence are not affected by anticholinergic agents used for associated extrapyramidal symptoms.

An 18-year-old man whom we treated sequentially with haloperidol, chlorpromazine, and fluphenazine had 14 episodes of enuresis or urinary incontinence in the first 65 days of treatment; yet he stabilized on 1200 mg of chlorpromazine and his incontinence did not recur.

Enuresis and urinary incontinence are common phenomena in diseases affecting the basal ganglia (2), e.g., parkinsonism, idiopathic orthostatic hypotension, and striatonigral

degeneration (1). Neuroleptics alter the balance of central biogenic neurotransmitters and cause extrapyramidal symptoms. Furthermore, dopamine agonists may induce urinary retention. Bromocryptine, an ergot alkaloid with significant dopamine-agonist activity, is used to treat parkinsonism and is reported to be beneficial in unstable bladder disturbances with symptoms of frequency, urgency, nocturia, and urinary incontinence unresponsive to other drugs or bladder manipulation (3).

We concur with Dr. Shenoy's statement that α-adrenergic blocking actions do not adequately explain this phenomenon because of the absence of other systemic adrenolytic effects. It should be clarified, however, that primary enuresis in male children is not a disturbance of slow-wave sleep, nor is there a greater than chance occurrence of enuresis in any particular sleep pattern (4).

Enuresis and urinary incontinence in patients receiving neuroleptics may be other forms of extrapyramidal toxicity. Further study is warranted to clarify the prevalence and pathophysiology of urinary disturbances in patients treated with phenothiazine and other antipsychotic compounds. Correlating drug effects with neurophysiology may further our understanding of the action of these agents.

Time Orientation and Ghetto Patients

SIR: I was extremely disturbed after reading "Time Orientation and Psychotherapy in the Ghetto" (March 1980 issue) by Eric Lager, M.D., and Israel Zwerling, M.D., Ph.D. Although the intent of the article was good—to explain that long-term therapy can benefit ghetto patients if the therapist understands their present-time cultural value orientation—the article left a bad taste in my mouth.

There are some elements of truth in the notion "Live today before you die tomorrow." However, the idea that "appointments are never more than approximate schedules; they are kept according to 'black people's time' or 'Puerto Rican time' " is unacceptable. I base this assertion on 10 years of experience in treating ghetto patients. I currently work in a ghetto clinic and see about 125 patients, who are predominantly black. These patients keep their appointments or will call and arrange for another appointment if they are unable to come in. They know I expect them to be on time. The first time a patient arrives late I explain that if he arrives late a second time I will not see him. He will simply have to get another appointment.

I agree with the statement that the "most common cause for stormy reactions and treatment interruptions was the therapist's underestimation of the importance of the therapeutic relationship for the patient." I suggest that the therapist use the importance of the therapeutic relationship to encourage the patient to be prompt and to prepare for the future rather than simply excusing the patient's behavior as being culturally appropriate. It has been my impression that the ghetto patient who casually floats in late to his session is being "cool." It is extremely important that ghetto patients maintain some sense of power and control; to maintain this "overcompensatory grandiosity" they may initially attempt to downplay the importance of the therapeutic relationship by casually floating in late to their sessions. This behavior will continue unless the therapist makes it clear that it will not be accepted. Allowing this behavior to go unchecked only develops and reinforces a defense that undermines the necessity of being on time for work.

Dr. Lager and associates did make some good points which support my contention that their reasons for asserting that ghetto patients are never on time are incorrect. They noted that patients who tend to stay in treatment feel special. I agree with this as I have seen it in my practice. People who are "special" often have expectations placed on them which they are expected to meet. Thus, I explain to my patients that "rank has its price and privilege." As a result of the special status they derive from being involved with psychotherapy, I expect them to pay several prices, one of which is being on time. Compliance with this expectation is usually fairly high. Thus I have a hard time believing that their original lateness stemmed from an orientation toward time that was deeply rooted in their fundamental value system. This fundamental value is too easily stopped by a simple explanation of the importance of being on time and then by enforcing the consequences of arriving late. Of course, if the assessment of middle-class therapists is overloaded with misinterpretations of sexual and aggressive behavioral reports as being signs of impulsive behavior and therefore superego deficits, I would hardly expect such therapists to simply state that if the patient is late, he will not be seen.

Finally, I have not seen among my patients a tendency toward reduced self-awareness or minimal verbal communications about their feelings toward therapy. I have seen that there is an initial "cool" and, considering the high rate of institutionalization of ghetto patients, an appropriate distrust of therapists which does not allow the patients to talk about such issues. However, during the course of therapy that cool falls away rather quickly and one finds oneself with a very aware, sensitive patient. It is only then that a therapist realizes the danger of emotional life in the ghetto and the need to protect narcissistic vulnerabilities through the use of "being cool" and thus being late.

CARL C. BELL, M.D.
Chicago, Ill.

Dr. Lager Replies

SIR: The authors thank Dr. Bell for his comments. Our experience, however, has been that patients who are told firmly that they need to be on time before they have established a relationship tend to drop out in large numbers.

ERIC LAGER, M.D.
Philadelphia, Pa.

The Importance of Clinical Work to Psychiatrists

SIR: This is in response to "Rare Birds, Queer Ducks, or an Endangered Species?" by Sidney Werkman, M.D., "Factors in Medical Students' Choice of Psychiatry," by Paula F. Eagle, M.D., and Luis R. Marcos, M.D., and "Choosing Psychiatry: The Importance of Psychiatric Education in Medical School," by Arthur C. Nielsen, M.D. (April 1980 issue).

Another possible reason for the decline in medical graduates entering psychiatry is suggested by the fact that this decline began in 1965, about the same time that community mental health movement ideals began to influence psychiatry. The community mental health model, in addition to discharging into the community patients unable to care for themselves, displaces the hierarchical medical model by a team approach and a supervising or back-up model of psychiatric practice. Medical students see their psychiatric teachers supervising nonpsychiatric clinicians and administering hospital and academic departments rather than treating patients. They also see the resulting harm to patients. If students believe a doctor's job is to treat patients rather than solely to instruct others, they will be forced to look to other specialties. Academic psychiatrists might take Adolf Meyer's advice more seriously: ". . . all psychiatrists must remain active in the treatment of patients. In this way, the essential perspective of physician as clinician would not be lost, and his primary loyalty to the individual patient would not be forgotten." We might make working at least part-time as a clinician with seriously disturbed patients in an emergency room or psychiatric hospital a prerequisite for teaching medical students. If treating patients were made mandatory for administrative psychiatrists, patient care might also improve. Administrators would learn firsthand how their policies affected patients treated at their facilities. Until these changes are made, medical students may be wise to avoid a specialty that continues to move farther and farther away from providing direct patient care.

LEWIS GLICKMAN, M.D.
Brooklyn, N.Y.

Alcoholism: Mimicking Psychopathology?

SIR: In "Clinical Depression in Alcoholism" (March 1980 issue) Myrna M. Weissman, Ph.D., and Jerome K. Myers, Ph.D., suggested a high rate of psychiatric diagnoses in their alcoholic population. They stressed the need for adequate assessment of alcoholic patients and consideration of potential treatment for disorders and diseases other than alcoholism.

As the medical director of a large treatment center for alcoholics, seeing approximately 13,000 clients per year, I have found that this population commonly has psychiatric diagnoses of manic-depressive illness, varying types of schizophrenia, and major depressive illnesses. We have treated this population for these diagnoses and in approximately 95% of these patients the treatment has been ineffective when the primary disease of alcoholism has not been treated or has been treated ineffectively.

We conducted follow-up studies of patients maintaining sobriety who also carried major psychiatric diagnoses. In 98% of these cases, we found no evidence of abnormal mental states approximately 6 months to 1 year after onset of sobriety. It is our assessment, as well as that of others in the field of alcoholism, that the alcoholic disease process can mimic severe psychopathology during intervals between drinking episodes or during alcohol toxicity itself. We strongly recommend that no alcoholic patient be treated for psychiatric disorders until the primary alcoholism process has been arrested.

FREDERICK A. MONTGOMERY, M.D.
Yakima, Wash.

Dr. Weissman Replies

SIR: We thank Dr. Montgomery for his thoughtful letter and would certainly agree that acute alcohol toxicity can mimic a variety of other psychiatric disorders. However, this does not detract from our finding that some, but certainly not all, alcoholics do have other psychiatric disorders that are evident before the alcoholism and that seem to persist afterward.

A follow-up study using precise research diagnostic criteria of alcoholics who are maintaining sobriety 6 months to 1 year after the onset of sobriety would be quite useful. Such a follow-up might document Dr. Montgomery's clinical observation that a large percentage of these patients show no evidence of abnormal states even though they did so while untreated. It would also identify that subgroup who do have other psychiatric disorders which could be effectively treated. I am unaware of any published studies of this kind using systematic diagnostic procedures.

MYRNA M. WEISSMAN, PH.D.
New Haven, Conn.

Withdrawal States and Alcoholic Hallucinosis

SIR: In "Psychosis with Withdrawal from Ethchlorvynol" (February 1980 issue) Leonard L. Heston, M.D., and Donald Hastings, M.D., reported an unusually prolonged withdrawal state with psychotic symptoms occurring after abrupt termination of ethchlorvynol. Important features of this state included onset of extensive tactile, visual, and auditory hallucinations and the presence of a clear sensorium 8 days after the drug has been discontinued. Drs. Heston and Hastings did not comment on the status of the patient's vital signs during the initial period of his disturbance. A schizophrenic-like state, with continual auditory hallucinations, Schneiderian features, and affective blunting persisted for 18 months until the patient apparently ended it by self-administration of alcohol. Eventually the patient recovered completely.

Although Drs. Heston and Hastings speculated on the relationship between alcohol, ethchlorvynol, and the patient's psychosis, they overlooked the striking similarity between this syndrome and alcoholic hallucinosis (1). In the latter, during or after alcohol withdrawal the patient exhibits symptoms that are difficult to distinguish from schizophrenia, but does not exhibit the confusion commonly associated with withdrawal delirium. Although clinicians have frequently suspected an underlying schizophrenia and often attribute the patient's alcoholism to an attempt to "self-medicate" for

this condition, there seems to be no genetic background of schizophrenia associated with these cases (2, 3). In fact, alcoholism and schizophrenia are apparently infrequently associated (4). The symptoms often become chronic, although shorter courses are more common (1).

To my knowledge, a similar syndrome has not been associated with withdrawal from sedative drugs other than alcohol; perhaps this case is the first. The disappearance of hallucinations after alcohol intake may indicate that withdrawal of both alcohol and sedative-hypnotics produce hallucinosis by similar mechanisms and can substitute for each other effectively in its "treatment." Other questions remain unanswered, however, such as the possibility that withdrawal from alcohol itself caused the prolonged hallucinosis and why symptoms that were so resistant to pentobarbital during hospitalization were so dramatically affected by alcohol months later.

EDWARD L. MERRIN, M.D.
San Francisco, Calif.

Dr. Heston Replies

SIR: We thank Dr. Merrin for emphasizing different aspects of our case report, but we do not think there is a substantial argument between us. Of course alcohol must be considered in the total clinical picture; we suggested an additive or synergistic effect with ethchlorvynol. However, we think that alcoholic hallucinosis alone is an unlikely explanation of the clinical picture. Our patient's alcohol intake had not been excessive before the first hospitalization but he had been taking large amounts of ethchlorvynol over the years. (We regarded our medical history as unusually reliable.) We saw three possible explanations for the clinical phenomena observed. 1) Alcohol withdrawal alone. We considered this most unlikely because we know of no report of such prolonged withdrawal among the many thousands of patients who have been observed. 2) Ethchlorvynol withdrawal. This seems a better bet because the dose was so high, the period of use was so long, and the few reports in the literature are consistent. 3) Ethchlorvynol plus alcohol. This is our choice because the patient used both drugs, which are pharmacologically similar, so that substitution (in the pharmacologic sense) and interactions could reasonably be expected.

Our only possible disagreement with Dr. Merrin is a mild disclaimer. We think that comparable withdrawal syndromes occur involving glutethimide.

Minneapolis, Minn.

On Reading Lacan: Fundamental Concepts

SIR: In his review of Jacques Lacan's *The Four Fundamental Concepts of Psychoanalysis* (July 1979 issue) Garfield Tourney, M.D., stated that "to read and attempt to comprehend Lacan proves a near impossibility."

It is true that approaching Lacan's essays expecting to gain access to delineated concepts conveyed through the operation of logical, propositional reasoning is an exercise in futility. However, we should not read Lacan this way any more than a therapist should listen to a patient's expression with only that critical faculty which judges the veracity of propositions according to Aristotelian categories. Lacan's writings are examples of free associative cognitions and are essentially rich in nuance, metaphor, symbol, and evocation—in that ambiguous structure which is the fabric of dreams and which Freud designated collectively as the dream work in chapter six of the *Interpretation of Dreams*. Lacan's discourse requires an act of comprehension adequate to the human experience of ambiguous expressive meaning, an act of comprehension which is no less obscure when it is raised to the level of a "fetish" (literally, a disavowal), as Dr. Tourney suggested.

The density and overdetermination of Lacan's writing is disclosed through that special organ of sense Freud called evenly poised attention (*gelichschwebende Aufmerksamkeit*) (1), with its implication of bracketing the operations of judgment, cognition, and perception—characteristics of everyday understanding. Lacan should be read like the text of a dream, a good joke, or the fluid interplay of image found in such inspired poets as Rimbaud. The reader must preserve his or her capacity for surprise.

Lacan does not suffer from a "tendency to ambiguity" as a symptom. Before any judgment of obscurity or observation of symptomotology, human expression is essentially ambiguous and provisional; this fact enlivens Lacan's writings and is never lost sight of even in its explication. When reading Lacan we should not lose sight of the observation of his colleague and friend, Maurice Merleau-Ponty, that "the will to expression itself is ambiguous and contains a ferment that works at modifying it" (2). Lacan referred to this as the Discourse of the Other. Nurturing and conveying the ambiguity of experience is not the same as being lost in a web of words or defective reasoning.

This may also be seen from the perspective of reading Lacan in the tradition of the "increasing medical orientation of American psychiatry." A positive, productive approach to Lacan may also be found in the recent work on hemispheric lateralization of cognitive functioning. Following the inspiration of Bogen (3), we should read Lacan with the appositional logic of the right hemisphere that provides, as McLaughlin (4) pointed out, a neurobiologic foundation for the image-enriched, affective, and ambiguous Gestalten of primary process type cognitions.

Dr. Tourney criticized Lacan's writings for not being more propositional—that is, not being more consistent with the expressive intention of the left hemisphere. But can the left hemisphere criticize the right for seeing the world from a different angle? Isn't it amazing that both hemispheres could find a proper symphonic balance and compromise to produce a work as suggestive of novelty and as rich in expression as Lacan's? Lacan's work should be read as a melody, comparable to the great compositions of Mahler and Ravel. Ravel, when rendered mute with expressive aphasia, still pre-

served his melodic, rhythmic, and stylistic sense. If Lacan suffered from a propositional aphasia, it is then equally true that the preserved melodic sense will yield a productive reading of Lacan.

In closing, let us follow the suggestion of Dr. Tourney and take a phenomenologic reading of Lacan. Let us be guided by Lacan's own words in finding our way through his labyrinthine texts: "Without first racking our brains to understand this meaning, how can one translate what is not itself language? Led in this way to appeal to the subject, since it is to his account which we must transfer this understanding, we shall implicate him with us in a wager, a wager that we understand him and then wait until a return makes us both winners. As a result of continuing to perform this shuttling back and forth, he will learn quite simply to set the pace . . ." (5).

Correction

In "Psychological Manifestations of Nonbacterial Thrombotic Endocarditis" by Thomas B. Mackenzie, M.D., and Michael K. Popkin, M.D., in the August 1980 issue, the last sentence of the first paragraph on page 972 should be, "It is generally considered to be a hypercoagulable state." The staff regrets this error.

BOOK FORUM

NANCY C. ANDREASEN, M.D., EDITOR

The Powers of Psychiatry, *by Jonas Robitscher, J.D., M.D. Boston, Mass., Houghton Mifflin Co., 1980, 538 pp., $17.95.*

Dr. Robitscher was a lawyer before he was a doctor. Through medical school and psychiatric training, "some legal part of myself," he writes, "saw the psychiatrist-patient relationship through the eyes of a lawyer." Some legal part still does, if his book is an indication.

In a 538-page brief (it would have been longer, he says, without his able editor), he accuses psychiatry of many crimes. Psychiatrists, he says, give too many pills, push the ECT button too often, and recommend unjustified lobotomies. They meddle where they shouldn't, tarring politicians with armchair diagnoses, pontificating about world affairs, and handing down Olympian judgments about social problems. Judges and juries actually *listen* to them (this will surprise many psychiatrists) and base decisions about who gets custody of children, who goes to jail or goes free, who gets a job or does not, on dubious psychiatric advice. Psychiatrists open the door for draft-dodging and abortions because they dislike war or favor abortions, or simply for money.

Psychiatrists are not scientific. They are not really physicians. They pretend to be both, and society buys it. As a result, psychiatrists have become enormously powerful. They have replaced priests as the preeminent authority on what is "right and wrong, moral and immoral, expedient or inexpedient."

No one will question the abuses listed by Dr. Robitscher. Some will question how widespread they are. Few will disagree that psychiatrists dislike hearing about abuses and prefer to look the other way.

Many will question how powerful psychiatrists have become. Dr. Robitscher's book is not a Szaszian polemic—he thinks psychiatrists often do good, maybe more often than not—and he occasionally is caught in contradictions. Here is a charming example:

> During several years when I was a consulting psychiatrist for a prison, I learned the excitement and pleasure of wielding great power—the thrill that came with the ability to confer liberty, the thrill that came from knowing I could deny liberty by not recommending parole. . . . I learned that there were institutional rules that took precedence over clinical judgment. For instance, a patient should not be recommended for parole too early, no matter how I saw his psychiatric status, since the parole board would not favorably consider such a request. . . . I learned to tailor my psychiatric evaluations to the facts of prison life.

This, perhaps, better reflects the perception of most psychiatrists of their professional life than does the untrammeled exercise of naked power described in this book. At a time when fewer medical students are entering psychiatry, when psychiatrists are lampooned in fiction and by the press, when restrictive legislation makes the practice of psychiatry almost impossible, psychiatrists should read this book just to raise their spirits. They may not be as powerful as Robitscher says, but in bad moments they might like to think they are.

On abuses this is a serious, carefully documented book by one of our leading doctor-lawyer scholars. It should be taken as seriously by readers inside the profession as it undoubtedly will be taken by those outside.

BRIEF MENTION

Adjustment: The Development and Organization of Human Behavior, *by R. Douglas Whitman. New York, N.Y., Oxford University Press, 1980, 275 pp., $15.95.*

This book was designed as a text for use in courses dealing with adaptation and adjustment. Like many texts designed for use in undergraduate psychology courses, it could also serve a useful educational purpose for residents or even for senior clinicians who wish to expand or update their knowledge of psychological research and theory in the area of stress disorder.

They should not buy this book for that purpose, however. It is nicely designed and printed, bringing to mind the old aphorism that you can't judge a book by its cover. The author has tried to cover more material than he knows well, and as a consequence the treatment is intolerably superficial. He attempts to discuss such diverse and unrelated areas as the scientific method, basic genetics, social psychology, psychodynamics, the nosology and classification of disorders, the etiology of various psychiatric disorders, and treatment. His references are often outdated and sometimes wrong, and the contents tend to be excessively sketchy and glib. Stress and stress disorders receive very little attention.

Biological Studies of Mental Processes, *edited by David Caplan. Cambridge, Mass., MIT Press, 1980, 322 pp., $24.95.*

Psychiatry has always enjoyed a broad frontier with neurology. Recently, psychiatrists have become more interested in the biology of brain function and its relationship to the disease process, while neurologists, neuropsychologists, and psycholinguists have been increasingly successful in mapping out areas of brain function and abnormality. This book provides a useful introduction or overview of recent developments in cognition and language. It condenses a great deal of useful information in a single volume.

It contains 15 chapters that fall naturally into three sections. The first section contains studies of the maturational

component of cognitive development. The second section examines aspects of language development. The third section focuses on neural mechanisms underlying language in the adult. Topics such as cerebral dominance, the neurology of the aphasias, and current theories of psycholinguistics are interlaced through these chapters. The authors represent a blend of talented young investigators and distinguished senior researchers, such as editor David Caplan, Noam Chomsky, Thomas G. Bever, Mary-Louise Kean, Merrill F. Garrett, Edgar B. Zurif, Jason W. Brown, and Norman Geschwind.

After this enthusiastic recommendation, however, a caveat should be added. People who are experts in language are not necessarily experts in communication, and some of the concepts conveyed in this book are likely to be difficult or unfamiliar. It is an excellent book for those who wish to venture into the new frontiers of neuropsychology and psycholinguistics, but the journey will require time and intellectual effort for most readers who pick up this book.

Migraine: The Facts, *by E. Clifford Rose and M. Gawel. New York, N.Y., Oxford University Press, 1979, 104 pp., $10.95.*

This is a clearly written and well-designed volume directed to lay readers who wish to learn more about migraine. It is the sort of book that a psychiatrist may prescribe for his or her patients to relieve their aching curiosity, if not their aching heads. It discusses the definition of various types of headache, causes of headache, predisposing factors, pathophysiology, and treatment. The presentation is simple and clear, and an abundance of excellent drawings supplements the discussion in the text.

Fridericus, *by Frederic F. Flach, M.D. New York, N.Y., Lippincott & Crowell, 1980, 254 pp., $9.95.*

Frederic F. Flach, a New York psychiatrist whose previous work has included biological research in depression and several books on psychiatry addressed to lay audiences, has now written his first novel. Drawing on his personal experience of having found a book written about melancholia in the seventeenth century by one Fridericus Flacht, he has let his imagination consider the possibility and implications of reincarnation. The protagonist in this novel, Dr. Frederic Pleier, is a New York psychiatrist who discovers that he may be the reincarnation of a seventeenth-century physician who lived in Worms during the dreadful pestilence of the Thirty Years War. Dr. Pleier finds himself intermittently subject to periods of disappearance, during which he appears to be mysteriously drawn back into the seventeenth century to solve and work through some unfinished business. Naturally, his twentieth-century friends and colleagues are concerned. Is he crazy? Is he suffering from seizures? Is he depressed? Should he receive psychoanalysis or ECT? The novel shows many signs of being a first work, such as lack of personal distance and shallow characterization. Nevertheless, its plot line is well drawn, and suspense is well handled. Some psychiatrists should enjoy reading this first effort by one of their colleagues.

N.C.A.

Handbook of Geriatric Psychiatry, *edited by Ewald W. Busse, M.D., and Dan G. Blazer, M.D. New York, N.Y., Van Nostrand Reinhold Co., 1980, 532 pp., $34.50.*

Try as one may, it is impossible to do justice to a handbook of this high caliber in the space allotted here. It is a handbook in every sense of the word and an excellent one at that, for it is a ready reference of eclectic orientation to the theory and practice of geriatric psychiatry. Its separate essays are broad and well done, its authors are highly skilled physicians and biomedical and behavioral scientists of equal capabilities. It is a true vade mecum, and I am tempted to quote whole pages of it.

The first 10 chapters are devoted to the biological and psychological bases of geriatric psychiatry. These cover diverse aspects of the specialty—its theories and processes, the neuroanatomy and physiology of aging, the neuropharmacology, perceptual changes, psychology, and social factors, among others.

The second section is concerned with diagnosis and treatment in the light of *DSM-III* with its multi-axial approaches to diagnosis. The material is timely and includes data that will facilitate understanding of the problems at hand as well as indicate approaches to treatment.

The third section of the work has to do with future directions and presents two fine chapters, one by George Maddox on the "Continuum of Care: Movement Toward the Community" and the editors' final discussion, "The Future of Geriatric Psychiatry." Together the chapters indicate that the physician who would practice geriatric psychiatry in the future will have to broaden his or her outlook and develop a working knowledge of the total delivery of health care.

Various theories of biological aging are discussed. The authors note that for all races there are 128 women for every 100 men after the age of 55. After the age of 75, in the year 2000 there will be 191 women to 100 men.

Current thought indicates that aging per se does not independently alter personality, but the passing of time and the biological state plus events in the life cycle do influence both personality and behavior. Experiences become increasingly different rather than similar as a person ages.

Neugarten is quoted as believing that there are sex differences in certain personality traits in late life. Men are more affirmative and likely to ally themselves with groups of men; women are more individualistic.

Various psychological theories are discussed. Apparently people whose lifestyles are altered least exhibit the highest life satisfaction. To attain long life and happiness, continuity is preferred. Prejudice, minority status, and gerontophobia are considered; the health disciplines have these to deal with along with economic problems and social isolation. These plus many other complaints often make the physician feel he or she has little to offer. Social theories are discussed. One of these, which must appeal to the practicing physician, is the "activity theory" holding that the maintenance of activity is important to most individuals as a basis for maintaining satisfaction, self-esteem, and health. The doctor understands that.

Unfortunately, some elderly people have minority status thrust upon them; these individuals have little to look forward to—the gerontophobia seems to move from disliking aging things to disliking the elderly. Again in these situations the doctor feels impotent. At the White House Conference in 1971 it was estimated that four million of the twenty million

individuals over the age of 65 have suffered moderate to severe psychiatric impairment from various causes. Of this four million, 20% were said to be not legally competent.

Traditionally it has been assumed that senile dementia is due to cerebral arteriosclerosis, but more recently multiple infarctions have been held responsible for approximately a third of the dementias; the majority of these are of the Alzheimer type and unrelated to arteriosclerosis.

Evidence suggests that there is a fundamental relationship between the aging process and changes in neurotransmitter substances in the brain and in other regions of the body. Environmental and genetic influences may be interposed that will alter the rate of aging and affect the time when age-related psychology may appear. Many of the phenomena of aging may ultimately be traced to neuroendocrine factors or anatomic loci in the brain. We need to learn a great deal more to determine the importance of neurotransmitter substances to aging and the degree of control that might be developed by their manipulation.

As to the neuropharmacology of aging, it is estimated that almost a third of the people over 60 receive some kind of psychotropic medication in the course of a year. The chapter discussing this topic is excellent. It considers many of the medications used by the elderly and also considers anxiety and sleep disorders.

These are simply snippets of the many fascinating discussions that cover all aspects of the lives of the elderly. I am a bit apologetic in offering them, but I have hesitated to get into the chapters on memory, cognition, and the physical changes that occur in older years, for these are of particular interest to me and I would devote too much review space to them. Suffice it to say this is a well written, complete, and excellent reference book. At the risk of sounding trite I add that it should be in the hands of everyone who deals with elderly patients. There is information in it which will at some time come in handy, that I can guarantee.

F.J.B.

The Lust to Annihilate: A Psychoanalytic Study of Violence in Ancient Greek Culture, *by Eli Sagan. New York, N.Y., Psychohistory Press, 1979, 224 pp., $12.00.*

This book purports to be a study of violence in ancient Greek culture, a study informed by psychoanalytic principles. It is also an attempt to say something about universals in human violence, and as such it frequently draws parallels between ancient and modern political and military behavior. It is this attempt to use ancient Greece as a case study of human violence which holds interest for psychiatrists.

This slim volume contains many interesting ideas and insights about ancient Greek culture. Although not a professional student of Greek culture, Eli Sagan, a sociologist with a psychoanalytic bent, presents some fresh perspectives on the violent side of Greek culture. His speculations about conflicts of authority that permeate the *Iliad,* about the particular oedipal resolution suggested there, about how conflicts within the group are resolved by projecting hatred onto a common enemy, are of great interest. One can also learn a great deal from his observations of Greek tragedy, and he has some astute discussion of the pained and painful family relationships represented therein. His analysis of Thucydides' great history of the Peloponnesian war, Greek tragedy acted out on the stage of politics and murderous warfare, draws our attention to modern rhetoric on the justification of wars. I also think there is something to be said for the author's contention that Judaism and, later, Christianity introduced ideals of love and compassion that were certainly not emphasized (although not absent) in Greek civilization. For all these things, the book is worthwhile, and I believe many readers of this journal could read it with profit.

I have, however, a number of serious reservations about this work. First, the author is not clear on when he is talking about something uniquely violent in Greek civilization, or about violence in much or all of human civilization. I am always uncertain about what his "standard meter bar" is for measuring the Greek "lust to annihilate." Warfare, and all that went with it, was pretty grim in the ancient world (as in the modern). The book is strangely unhistorical in that regard. The Persians were not exactly nice guys either. The Romans had at least an average amount of military and political cruelty, and imperial Rome had quite a taste for popular sadism in the public forms of entertainment. The ancient Hebrews, by divine command, could be ruthless with their enemies. King Saul fell out of favor with God for not exterminating every man, woman, baby, and beast of the defeated Amalakites. War is hell, war was hell, and in the ancient world to be a loser was to be in the lowest circle of hell.

The author acknowledges, but to my mind does not take seriously enough, the facts about war and violence waged under (and sometimes in the name of) Christian civilization. I agree that ideals about peaceable resolutions and brotherly love fostered by the monotheistic religions are good and desirable and may, ultimately, make a difference in human behavior. But surely only the most naïve students of history would predict when these ideals will make enough of a difference to radically alter the story of war and destruction that has gone on in modern times.

Further, if the author is doing a psychoanalytically oriented analysis of values of Judeo-Christian civilization in comparison with Greek civilization, he must take into account the totality of the values in the former. Greek tragedies reveal a view of the gods as capricious and cruel, but what about the central image of Christianity—a deity who wants to have his own son suffer cruel torture on a cross? Surely a balanced analysis must take that into account and at least consider the relation of the crucifixion story to the question of the psychology of violence. After all, for centuries the persecution of the Jews was justified in terms of their alleged role in that story.

Another criticism comes from my bias as a Grecophile. I do not think the author has very much empathy with ancient Greek civilization. He seems on a crusade to magnify the bloody aspects of Greek civilization and gives us an unbalanced view (in the name of correcting other unbalanced views). I also see the author's solution to human violence, the universal establishment of democratic socialism, as a bit naïve and anticlimactic. It is not that I am against democratic socialism (I am more for it than for other political systems), but surely any student of human violence must take seriously a tragic view of the side of human life, and that tragic view was certainly brilliantly articulated by the Greeks. In short, I suspect that the author has not made explicit enough his own values in this inquiry, while he argues the impossibility of value-free social science.

Finally, the author is not as original (but also not as alone) as he seems to believe. With wider reading, or wider consultations within the field of ancient history and civilization, he would have discovered views relevant to his own on the combative and violent side of Greek life, e.g., Badian (1) and Havelock (2). Similarly, his discussion of the Oedipus complex is too bookish and could have been enhanced by consulting with clinicians who use the concept in their daily work.

BENNETT SIMON, M.D.
West Newton, Mass.

Psychobiology and Human Disease, *by Herbert Weiner, M.D. New York, N.Y., Elsevier, 1977, 651 pp., $42.50.*

Over the past 10 years developments at the frontiers of medicine have challenged traditional psychosomatic concepts and have created exciting opportunities for research on the mind-body problem. At the same time the increasing complexity of biomedical science has made it difficult for psychiatrists to stay abreast of medical knoweldge and maintain the integrated overview of disease processes that has always been the desideratum of the psychosomatic approach.

In this context Herbert Weiner's extraordinary book is a timely and important contribution. He has prepared authoritative reviews of seven familiar medical disorders that are traditionally associated with psychosomatic medicine. These include peptic ulcer, essential hypertension, bronchial asthma, Grave's disease, rheumatoid arthritis, ulcerative colitis, and regional ileitis. For each he presents a synthesis of current information on pathogenesis and natural history drawn from disciplines ranging from sociology to molecular biology. In the process, he presents each disorder as representing a physiological system and a medical subspecialty. He also reviews the history of psychosomatic approaches to the seven disorders and subjects these approaches to critical analysis in the light of the latest biomedical research.

By presenting these reviews Weiner accomplishes several aims. Taken separately, each review constitutes a lucid and authoritative status report that provides psychiatrists with a synthesis of information not readily available elsewhere. Together they give a history of psychosomatic approaches, concepts, and methodology that shows the origins of current trends. In this context Weiner's detailed critical analysis of experimental design is especially interesting. The reviews also serve to introduce the more technical aspects of biomedical science, including important developments at the molecular level in immunology and cellular biology. Finally, Weiner uses the synthesis of material from various disciplines to make creative suggestions for future research.

In the last chapter Weiner goes beyond the specific disorders to consider general issues in the psychobiological approach to human disease. He reexamines fundamental questions in psychosomatic medicine, such as the problem of the transduction of experience into changes in physiological state. Here he draws extensively from current research in neurobiology. He warns repeatedly against the dangers of oversimplification and premature closure. In the review chapters he indicates that each of the seven entities may actually represent a group of disorders brought together because of clinical similarities, and each may arise from heterogeneous factors and processes.

The book represents a prodigious accomplishment. Weiner seems to be at home with each physiological system and with each scientific discipline. He has given the book the unity of style and approach that can be found only with single authorship. At times it is difficult to read because the material is dense and complex. The theoretical material in the last chapter requires careful study. However, the effort involved in reading the book will be richly rewarded.

Trainees at all levels are likely to find valuable information and concepts in Weiner's book. Even the most skeptical medical students would appreciate Weiner's approach. Psychiatric residents, faculty members, and senior clinicians might all benefit from the scholarship that has gone into the preparation of the book. It would be an important addition to the library of any consultation/liaison service. It would be especially useful for anyone who is involved in a career of psychosomatic research.

The heuristic value of this book comes in part from Weiner's meticulous attention to detail. However, one of the themes that sounds through the details most clearly is the enduring quality of clinical observations.

PETER REICH, M.D.
Boston, Mass.

The First Year of Life, *edited by David Shaffer and Judy Dunn. New York, N.Y., John Wiley & Sons, 1979, 211 pp., $22.50.*

Drs. Shaffer and Dunn, critical clinicians themselves, have attempted in this book to bring together a group of authors whom they asked to provide some well-reasoned material on the later implications of early childhood experiences. The authors, who either present their own research or have prepared a critical review on a particular aspect of the theme of the book, are all highly regarded European researchers from the fields of psychology, neurology, and psychiatry. They make the book an up-to-date document on the topic at hand.

The book is divided into two sections: a theoretical section and a practical one presenting specific studies. The first section deals with such issues as the techniques and problems encountered in the study of social behavior during the first weeks of life (by M. Packer and D. Rosenblatt), the continuities and discontinuities of individual differences (by J. Dunn), and cross-cultural perspectives on social relationships in infancy (by N. Burton Jones, R.H. Woodson, and J.S. Chisholm). All of these chapters present a good summary of current knowledge but are at times so condensed that the uninitiated reader may be overwhelmed by the number of studies each author reviews and consequently unsure of the relevance of specific investigations.

There are, however, exceptions. A.F. Kalveboer, who is a member of Heinz Prechtl's group in Groningen, gives a succinct description of this group's work on the neurobehavior-

al sequelae of pre- and perinatal complications, and Arnon Bentovim tries with some success to integrate psychoanalytic concepts with recent research findings in child development.

The best of the book, at least for the practicing clinician, is the second section. Here A.M. and A.D.B. Clarke give a superb overview of the limited effect of early experience on later development. Their array of well-documented studies showing how later corrective experiences can ameliorate early caretaking damage is impressive and convincing. F. Hall, S.J. Pawlby, and S. Wolkind continue by presenting more follow-up data on their excellent studies correlating a woman's past social experiences with her later caretaking practices. These authors clearly document that mothers who come from disrupted backgrounds stimulate their infants significantly less both vocally and in touching than do normal controls. Olwen Jones touches on an issue frequently discussed among developmentalists today, namely, the possibility that parents try to make up for neurological or cognitive deficits of their children by providing them with extra stimulation. Thus Jones shows that mongoloid children are stimulated more by their mothers in a number of situations than are normal children.

The last chapter of the book reports on the 8-year follow-up investigation of Barbara Tizard's well-known study of institutionalized children in London. Since some of these children had been adopted or reunited with their biological mothers, Tizard was able to evaluate the effects of various caretaking regimens on the later school and behavioral functioning of these children. Her results make fascinating reading and demonstrate that the study is obviously one of the best of its kind. Her chapter, together with some of the others mentioned above, makes this book an important addition for the clinician interested in the field of infant development.

KLAUS MINDE, M.D.
Toronto, Ont., Canada

Family Therapy of Drug and Alcohol Abuse, *edited by Edward Kaufman and Pauline Kaufmann. New York, N.Y., Gardner Press (Halsted Press, John Wiley & Sons, distributor), 1979, 272 pp., $24.95.*

Innovative and informative are two adjectives I would use to generalize about this book. The first of two major sections, titled Drug Abusers, contains 10 chapters; the second section, Alcohol Abusers, consists of 7 additional chapters. The authors are many, yet there is a surprising continuity and clarity.

A theme running through the entire volume is that people who abuse alcohol and drugs do so through learned behavior. This is not to imply that family therapy in its various forms can be considered a panacea, but it must be included in the therapeutic armamentarium and given a relatively high priority. Overall, this is a readable and useful book, highlighted by several chapters, notably chapters 1, 4, 9, and 10 in the first section and chapters 11, 12, and 15 in the second. Brief comments on these follow.

Chapter 1, "Constructing a Therapeutic Reality" by Salvador Minuchin, M.D., presents an excellent overview of the field with a theoretical basis and a concept of family relationships. The author makes some critical points: "Being correct has nothing to do with relevance. The therapist must learn to focus on that which is relevant. Truth needs to be relevant." Minuchin emphasizes the active process in therapy as dynamic and changing with the specific goals.

M. Duncan Stanton, Ph.D., and Thomas C. Todd, Ph.D., collaborated to coauthor chapter 4, titled "Structural Family Therapy with Drug Addicts." Their major points are that blame must not be affixed to the parents and that there is "no concern with insight or awareness but rather a focus on contemporary issues with a fair degree of success." They also emphasize the importance of having an active, involved therapist who must also be flexible, supportive, accessible, and enthusiastic. I found their method and descriptions apt and workable.

"Drug Abusing Families: Intrafamilial Dynamic and Brief Triphasic Treatment" by Dennis M. Reilly, M.S.W., introduces brief, time-limited, conjoint family therapy as an effective treatment modality. What was particularly refreshing in this chapter was the observation that to borrow techniques from other family therapy schools of thought constitutes a distinct positive advance. The author deals with how the unhealthy situation can be changed rather than how the situation developed, which, of course, is mandatory in brief therapy.

Section two starts out on a high note with "Family Therapy with Alcoholics," a review by Peter Steinglass, M.D. This is a particularly provocative, exciting chapter as well as the longest one in the book. Dr. Steinglass admonishes the reader that there is good supporting evidence that family therapy has value and is ardently boosted by its enthusiastic advocates. We must continue to objectively evaluate and assess this therapy, as we do any new treatment procedure.

Donald A. Cadogan, Ph.D., in "Marital Group Therapy and Alcoholism Treatment," reinforces what other authors, especially Stanton and Todd, have stated: that active involvement reaps more positive results than therapy by the withdrawn expert silent observer.

My major criticism of this book lies not so much with the content but with the too frequent typographical errors, which suggest to me an unnecessary sloppiness on the part of the proofreader and, sad to say, detract from the total enjoyment of the book—but not enough so that it cannot be recommended. The typographical errors fortunately are not reflected in the major ideas expressed by the authors. However, in any scholarly text, I believe it is particularly important that the proofreading be circumspect and accurate.

For those entering the field of family therapy, for those already involved in family therapy, and for any therapist who might be contemplating its use for alcohol and drug abusers, I heartily recommend this volume. It presents clear theoretical frameworks as well as many practical suggestions for implementing the theory and has enough introspection on the part of the various authors to provide further exploration and examination of this interesting modality.

HOWARD A. WINKLER, M.D.
Tucson, Ariz.

Principles of Clinical Psychiatry, *by Arnold M. Ludwig. New York, N.Y., Free Press (Macmillan Publishing Co.), 1980, 242 pp., $22.95.*

Selling textbooks of psychiatry must be a tough business. Medical students sometimes buy one but rarely read it. Psy-

chiatric practitioners usually possess an antique version, while academic purists disdain them. Examples that survive this hostile environment tend to focus narrowly on the "quick and dirty" approach for students or an increasingly mammoth, encyclopedic format with a thousand authors and stultifying prose, all priced for the OPEC market.

Arnold Ludwig's *Principles of Clinical Psychiatry* is not just a new entry; it's a very different animal. Organized around principles of clinical logic, it uses the "pearls of wisdom" approach favored by a few dimly recalled professors of clinical medicine from one's undergraduate days. The book describes major psychiatric illnesses crisply and systematically in terms of cognitive, emotional, perceptual, physiological, and behavioral disturbances. There are many tables of specific clinical features of particular illnesses, "clinical alert" charts consisting of historical and psychopathological features to clarify differential diagnosis, and many diagrams to explain real or putative mechanisms whereby psychiatric conditions develop. Ludwig's focus is assertively medical in the best sense. He likes to observe and examine, diagnose and treat. He eschews the fuzzy and emphasizes the soundly proven treatments, which usually means somatic ones. All of this has a no-nonsense aura, but Ludwig is never strident or sarcastic toward the time-honored, if scientifically unproven, therapies, which are, of course, primarily psychosocial.

What then are the flecks in the varnish? For one thing, the book predates *DSM-III*, while evidently anticipating it by studiously avoiding the moribund *DSM-II*. For a diagnosis-first clinician, this entails some obvious problems in organization and definition. All big-league depressions are classed within a rubric (and chapter) entitled "The Psychoses," whether or not psychosis is actually present. This is misleading. Grandiosity is cited elsewhere as weighing toward a diagnosis of schizophrenia, even though "grandiose themes are also common in manics." Agoraphobia seems confused with panic disorder *(DSM-III)*. Ludwig dismisses the diagnosis of borderline personality as a "wastebasket" somewhat too peremptorily. Lots of clinicians may have foundered on this one, but there are some clinical data and clarity is beginning to emerge. The concept of masked depressions is approved despite the general consensus, at least among academics, that this topic holds more dangers than rewards.

On the whole, problems of psychiatric taxonomy are handled gracefully enough, since the focus of the text is on how to think and judge. Of course, this cannot be separated completely from how to label.

At the treatment level, more problems crop up. The optimum lithium level for manic-depressive illness is cited as 1.2–1.8 mEq/liter, high by current standards. Phenelzine dosage is recommended to top out at 60 mg per day on one page and 75 mg per day on another, even though the *Physician's Desk Reference* sanctions 90 mg per day. The treatment of panic disorder whether or not associated with agoraphobia is not really clear at all. Ludwig suggests that monoamine oxidase inhibitors may be useful but does not clarify one of psychiatry's cleanest and most effective drug treatments—tricyclics or monoamine oxidase inhibitors for panic disorder.

The layout of the book is readable even though double-column in format, and the text is not spaced too tightly. The many diagrams that compress and codify some information, such as differential diagnosis, confuse other areas. A mandala-like, print-laden "personality wheel" may make some sense but seems more astrological than clear and medical. A flow chart of the metabolism of alcohol tries too hard, needs color for clarity, and looks like a bowl of spaghetti.

Topically, the emphasis on adult psychiatry legitimately excludes child psychiatry. Nevertheless, Ludwig's straightforward approach could have been usefully applied to at least a few conditions in child psychiatry, such as attention deficit disorder and separation anxiety disorder, which have adult sequelae. The chapters on psychosexual disorders and psychological factors affecting physical illness are skimpy to say the least, while organic brain syndrome receives perhaps too extensive coverage. Not surprisingly, Ludwig's chapter on drug habit disorders is excellent despite my reservations about its graphics.

The index is a real disaster. It is much too short for precise reference. For example, the controversial condition "hysteroid dysphoria" appears in bold face type on page 137 but is totally absent from the index. Textbooks need obsessionality in the index as much as they need to avoid it in their prose.

MICHAEL SHEEHY, M.D.
New York, N.Y.

The Psychobiology of Sex Differences and Sex Roles, *edited by Jacquelynne E. Parsons. Washington, D.C., Hemisphere Publishing Corp. (New York, N.Y., McGraw-Hill Book Co., distributor), 1980, 304 pp., $18.95.*

One will be gravely disappointed if one expects to find in this book an answer to the perennial question; "How do psychobiological, psychological, and social forces interact to shape sex role behavior?" However, if one expects to find a review of the current, relevant literature in this area with appropriate critique, one will be unusually pleased.

This volume grew out of a conference sponsored jointly by Smith College, the Five College Women's Study Committee, and each of the affiliated institutions—Mt. Holyoke, Hampshire College, Amherst College, and the University of Massachusetts. The conference was designed to meet what was perceived to be a growing need in the Five College Women's Study Program; that is, a need to integrate what was new in the psychological and social sciences in regard to the development and maintenance of sex roles. Experts who could integrate and evaluate biological and psychological viewpoints on important topics were brought together and asked to present their critiques of the various areas.

The book is divided into four sections: Psychosexual Neutrality, Sexuality, Women's Reproductive Systems and Life Cycles, and Cyclicity and Menstruation.

The chapters in the first two sections focus on gender role dimorphism, those in the last two sections on patterns of fluctuation in female behavior that have been linked theoretically or empirically to biological process. Dr. Parsons asks in the first chapter, "Psychosexual Neutrality," Is anatomy destiny? She concludes that cross-cultural and cross-species evidence has not yielded many unequivocal answers. It is her belief that there are some near universals—spatial skills and aggressiveness—that reflect a major component of biological differentiation, but even these behaviors differ cross-culturally and are highly malleable. It is her impression that other roles, like child care or defense, are consistently assigned to one gender or another but biological processes are

not the differentiating factors. She also concludes that the degree of gender dimorphism varies markedly across cultures; however, proscriptions and penalties for deviance from cultural norms have not been adequately investigated. She feels that gender dimorphism reflects the influence of biological, historical, psychological, and sociological forces.

The following chapters address in more detail the biological, psychological, and sociological bases of sex-related differences. In particular, the chapter by Broverman, Klaiber, and Vogel looks at gonadal hormones and cognitive functioning. One of their conclusions is that gonadal hormones are psychoactive. Estrogen and testosterone appear to have similar effects on the CNS; that is, both appear to act as central adrenergic stimulants, possibly through their regulatory effect on enzyme monoamine oxidase. These authors also feel (on the basis of their research) that high dosages of sex-appropriate gonadal hormones appear to alleviate depressive symptoms.

In the next chapter, Alexandra Kaplan looks at human sex hormone abnormalities viewed from an androgynous perspective—a reconsideration of the work of John Money. Of particular interest in this chapter is Kaplan's defense of the concept of androgyny, which in its simplest form means an equal balance between masculine and feminine characteristics. From a research point of view, the concept of androgyny increases the number of categories of human sexuality and sex role behavior and allows the researcher to look at psychological sex in a more sophisticated way.

Section two looks at human sexuality, heterosexuality, and homosexuality. The first chapter, by Dr. Rigby, reviews the biochemical and neurophysiological influences on human sexual behavior. The second chapter, by Dr. Bahlburg, reviews current thinking in regard to the biological and hormonal bases of homosexuality and concludes that homosexuality in general cannot be explained by endocrine abnormalities in adulthood. There is, however, some evidence from animal research that there may be prenatal sex hormone differences. These findings are not uniform, and their applicability and interpretation are still open. It may be possible that prenatal hormone abnormalities contribute to the development of sexual orientation in a minority of homosexual subjects, but this has not been sufficiently documented. The following chapter, by Dr. Falbo, looks at a psychological model of human sexuality.

Section three, Women's Reproductive Systems and Life Cycles, is perhaps the most interesting section. In particular, the first chapter, "American Birth Practices: A Critical Review," looks at the relationships between women and the social and technical practices associated with childbirth in American society from a historical point of view. It provides a critical insight into the changing patterns of delivery in the United States today and their impact on mothers and children, an important area of considerable research interest today. The authors conclude that the major hazards of childbearing have not been reduced by modern technology and efficient hospital procedure and that class differences in the safety of childbearing persist. They agree that adequate pre- and postnatal care as well as the health benefits of standard and natural delivery procedures would enhance both the physical and emotional experiences of delivery, which, in their opinion, are enjoyed primarily by middle-class participants in natural childbirth.

Finally, the last section of the book looks at cyclicity and menstruation. The lament of the first author, Carolyn Wood Sherif, that the research literature on the relationship of the menstrual cycle to mood, affect, and behavior is fraught with research error and valueless is echoed in the succeeding chapter by Rossi and Rossi. The Rossis describe their research into body time and social time in the menstrual cycle in great detail.

This book is for teachers involved in courses having to do with sex differences in sex roles. It is unusual in that it is an edited volume in which all of the pieces seem to belong and to flow naturally from one another. The biological data flow into the psychological and social data easily, and earlier chapters make reference to later chapters and vice versa. If one wishes to answer to the nature-nurture conflict one must look elsewhere, for this volume does not give pat answers. It only poses new questions. It is not easy reading, but it is a valuable "state of the art" book that experts on sex role will use and reuse.

ELISSA P. BENEDEK, M.D.
Ann Arbor, Mich.

The Many Faces of Suicide: Indirect Self-Destructive Behavior, *edited by Norman L. Farberow, Ph.D. New York, N.Y., McGraw-Hill Book Co., 1980, 427 pp., $18.95.*

If we label certain behaviors as self-destructive we suggest that they resemble suicide and that recognizing their common motives and psychodynamics can increase our ability to understand and control them. We may also suggest that they are, like suicide, psychopathological and thus the rightful concern of psychiatrists. Most readers of *The Many Faces of Suicide* will wonder whether such labeling is justified or useful and will look to this volume for an answer.

Editor Farberow appropriately dedicates his book to Karl Menninger, who, in the 1940s, developed Freud's concept of the death instinct and identified its expression in a variety of self-destructive behaviors. The book deals with behaviors that Menninger and others regarded as partial or indirect forms of suicide, including drug and alcohol abuse, noncompliance with medical treatment, obesity, cigarette smoking, delinquency and criminal activity, and high-risk sports. Although the contributors are experts in their respective areas, most had not previously considered how the concept of self-destructive behavior might apply to their subject. Consequently the treatment they give this aspect varies. Some make it the central theme of their contribution, others include it among the issues they discuss, and still others mention it only in passing.

For the most part the behaviors considered in this book are long-term patterns associated with an increased risk of death but without acknowledged self-destructive intent. The concept of self-destructiveness proves difficult to define, however, and a host of adjectives, including self-defeating, self-injurious, and risk-taking, are used interchangeably by various authors. Is it, for example, self-destructive when a patient who has had myocardial infarct, using denial, resumes normal physical activity against medical advice? Is it self-destructive when, to maximize the pleasure of a jump, a skydiver opens his parachute at the last moment? Would we call self-destructive the action of a person who cuts himself to restore a feeling of aliveness? Calling such diverse behaviors self-destructive implies that they have something in common beyond an increased risk of physical injury or

death. But that something remains elusive. Many authors approach the concept of self-destructive behavior in an uncritical fashion with the result that it becomes overinclusive and unclear.

The book is not without merit, however. It contains a number of stimulating and useful chapters on various psychopathologic and nonpathologic entities. In a chapter on alcoholism, Connelly thoughtfully examines the dynamics of this disorder and its relationship to suicide. Lichtenstein and Bernstein do not regard cigarette smoking as self-destructive, but their critical examination of that possibility and close examination of the determinants of smoking make a valuable contribution. Simpson's review of self-mutilative behavior is both scholarly and thorough and will be welcomed by those who have to deal with patients who repeatedly cut or otherwise mutilate themselves. An excellent review of the problem of drunken driving and how it might be better controlled is provided by Selzer. Finally, chapters concerning prostitutes and people who intervene in violent crimes offer understanding of behaviors that seem foreign to most of us.

The Many Faces of Suicide is about a host of behaviors that are both troubling and difficult to understand. In examining them closely the authors often recognize adaptive efforts to have gone astray and attempts to cope with life even at the risk of death. Beyond this, they identify dynamic patterns that are as diverse and complex as those involved in suicide itself. Perhaps we should recognize the limitations of our knowledge and remain cautious about intervening in behaviors that we may wish to control because they pose a threat to our values.

RUSSELL NOYES, JR.
Iowa City, Iowa

Biofeedback and the Modification of Behavior, *by Aubrey J. Yates. New York, N.Y., Plenum Press, 1980, 504 pp., $24.50.*

The development of biofeedback had a revolutionary effect on psychology, psychiatry, and medicine in the 1960s and 1970s. Biofeedback offered the promise of better health through self-regulation using operant conditioning techniques. Early writings on biofeedback promised drug-free treatment for "psychosomatic" disorders. These predictions also forecast that biofeedback would open new frontiers in the treatment of many stress-related diseases. The response of the medical establishment to the enormous popularity of biofeedback ranged from excitement to skepticism. Research studies on clinical efficacy at first supported claims that biofeedback would replace medicines in the treatment of many psychosomatic, behavioral, and stress-related disorders. Popular publications were often too uncritical in touting the usefulness of this exciting new treatment. Now, however, with the publication of Aubrey Yates's *Biofeedback and the Modification of Behavior,* there is finally a comprehensive textbook on biofeedback that is a scholarly effort to review and organize the vast body of data on this treatment modality.

Yates's book is published by Plenum Press, which has shown a special interest in psychosomatic and behavioral medicine. Plenum's medicine and psychology editorial staff, headed by Leonard Pace, has demonstrated skill in the selection and support of their behavioral medicine series. This book represents a thoughtful and considered approach in attempting to unravel the controversies surrounding the efficacy and clinical applications of biofeedback treatments. Yates states in the preface his intention to review the large literature on biofeedback that has accumulated over the last 15 years. He accomplishes this task with great skill, citing more than 1,300 references. More importantly, he conveys a critical balance in his content and style that lends credibility to his conclusions and helps the reader to form his or her own.

The organization of the book is sensible. An introductory chapter on the antecedents and history of biofeedback is followed logically by a brief yet sophisticated review of instrumentation and methodology. Some readers who are new to biofeedback methods may find this review over their heads and might prefer a more elementary and practical text such as George Fuller's (1). Each of the three major divisions of biofeedback research is covered in separate chapters: "Voluntary Control of Muscle Activity," "Voluntary Control of Autonomic Functions," and "Voluntary Control of Electrical Activity of the Brain." A comprehensive chapter on other applications of biofeedback follows. These include alcoholism, asthma, bruxism, diabetes, eczema, hyperactivity, and insomnia. Each area is thoroughly reviewed, and references are current through 1978. This concludes the clinical portion of the book.

The next to last chapter on theoretical aspects of biofeedback is likely to be of interest primarily to the sophisticated reader. Throughout the book Yates carefully adheres to scientific rigor in his criticism of the research foundation on which clinical practice is based. In the concluding chapter, "The Promise of Biofeedback," he takes off his gloves and skillfully identifies those areas of biofeedback poorly supported by hard data. With tact and fairness he circumscribes those areas in which excessive claims have been made and those needing further research. Yates's criticism is balanced and optimistic. His willingness to openly criticize his colleagues' work is refreshing. I wondered if the geographic distance between Yates's homeland (Australia) and North America enabled him to be so incisive and direct in his dissection of the work of others.

A major strength of this book is the author's attempt to address the major controversies plaguing contemporary biofeedback research. These controversies include the following: 1) Does biofeedback add any significant benefit over relaxation training without feedback in producing relaxation? 2) Does biofeedback training permit generalization of relaxation from one area of the body to others? 3) Do different methods of inducing relaxation differ psychophysiologically or subjectively? 4) Do psychophysiological changes vary with subjective reports according to expectation? 5) How much can the favorable outcome reported in many studies be accounted for by placebo effect? 6) Are the machines really necessary?

Yates tackles these issues head on, supporting his arguments with critical reviews of relevant research. Clinicians will no doubt find fault with his obvious preference for rigorously controlled, laboratory-based studies over the nonspecific but powerful treatment effects often obtainable in the clinical setting.

The book has several features that might be considered weaknesses. The first is that Yates's organizational scheme for presenting his coverage of the three categories of biofeedback research (muscle activity, autonomic function, and

brain-wave activity) appears logical from the viewpoint of the functional organization of the nervous system but not necessarily from the clinical viewpoint. Many clinicians might prefer a "disease-oriented" organization to Yates's "functional" organization. Since the table of contents is not organized by disease, the index, while adequate, lacks sufficient cross-references. For example, eczema is listed only under that heading. A reader looking for sections on the clinical applications of biofeedback in the treatment of psychophysiological skin disorders, atopic dermatitis, dermatitis, itching, or pruritis would not find any page references in the index under those headings. This deficiency could be easily corrected in future editions and would be a useful feature for the clinician. Some clinicians might also object to the heavy emphasis on controlled group outcome studies and the paucity of case reports or longitudinal single case studies. However, my preference is to see individual case data presented in specialty journals such as *Biofeedback and Self-Regulation*, not in reference texts. Finally, the book is in no way useful as a practical guide for the clinician in the art and practice of biofeedback or behavioral techniques. For that the reader must look elsewhere.

This book is the best volume currently available for a thorough overview of the scientific basis of biofeedback practice. It is an essential reference text for anyone using biofeedback techniques in clinical practice and a valuable, comprehensive guide for the interested student, resident, or practitioner.

Basic Handbook of Child Psychiatry, Vol. 1: Development, *edited by Justin D. Call, Joseph D. Noshpitz, Richard L. Cohen, and Irving N. Berlin; Joseph D. Noshpitz, editor-in-chief. New York, N.Y., Basic Books, 1974, 691 pp., $35.50.*

Basic Handbook of Child Psychiatry, Vol. 2: Disturbances in Development, *edited by Joseph D. Noshpitz; Joseph D. Noshpitz, editor-in-chief. New York, N.Y., Basic Books, 1979, 722 pp., $35.50.*

Basic Handbook of Child Psychiatry, Vol. 3: Therapeutic Interventions, *edited by Saul I. Harrison; Joseph D. Noshpitz, editor-in-chief. New York, N.Y., Basic Books, 1979, 673 pp., $35.50.*

Basic Handbook of Child Psychiatry, Vol. 4: Prevention and Current Issues, *edited by Irving N. Berlin and Lawrence A. Stone; Joseph D. Noshpitz, editor-in-chief. New York, N.Y., Basic Books, 1979, 584 pp., $35.50 (4-volume set: $138.00).*

The field of child psychiatry has occasionally been taken to task for its presumed lack of cohesion and structure. It is not surprising, then, that there has been no single volume or set of books until now attempting to cover the ever-widening array of disciplines that make up the field. The recent publication of the *Basic Handbook of Child Psychiatry* belies this notion. This four-volume set is a truly magnificent piece of work. Enormously important in its own right, it will in time become a unifying milestone to child psychiatry in general. Unlike so many recent compendia, this is not a collection of previously published articles but a thoroughly integrated and coordinated effort on the part of Joseph Noshpitz and a group of hard-working co-editors and colleagues who spent more than six years soliciting, collecting, editing, and organizing some 250 separate chapters.

The authors are for the most part well known and distinguished. They represent no one school of thought or point of view; in fact, within these volumes can be found a balanced discussion of virtually every important developmental theory, method of child treatment, and aspect of childhood psychopathology.

The set of books is held together—as is the field of child psychiatry itself—by a developmental approach. Volume 1, perhaps the most ambitious of the four, is really three distinct units. The first 300 pages is a stepwise sequence of reviews of normal biological, psychodynamic, and psychosexual development from conception to late adolescence. The middle section of this volume contains roughly 40 separate chapters describing developmental variations, such as "The Adopted Child," "The Fatherless Child," "The Child Raised Overseas," "The Street Child," and another 10 chapters on children with a variety of major medical handicaps. Many of these submissions are extremely informative essays. The chapter on "Children of Different Ordinal Positions" by Edington and Wilson is particularly outstanding.

The final third of volume 1 is devoted to concepts and techniques of assessment. It is enriched by a number of unusual chapters on automated data systems, computer-assisted diagnostic techniques, and standardized data collection, which a less thorough and farsighted editor might not have thought to include.

The emphasis of volume 2 is on nosology, diagnosis, and descriptive pathology. After a fascinating summary of various diagnostic schemata not in use, the bulk of the volume proceeds to more than 30 separate reviews of the major child psychiatric syndromes, including school phobia, enuresis, habit disorders, minimal brain dysfunction, and childhood psychoses. Many of these are the equivalent of truly first-rate journal articles. The overview of the anorexia nervosa syndrome by Sours is one of the best on this subject I have encountered.

Volume 3 is constructed around theoretical and practical considerations of treatment. Since therapeutics remains perhaps the least agreed on area for all of psychiatry, it is not surprising that this volume contains some of the more controversial offerings. Although one obviously would not purchase every item in the store, the psychopharmacologists, family therapists, educational psychologists, child analysts, behaviorists, and counselors have clearly been given a fine opportunity to display their wares.

The fourth and final volume is addressed to prevention and to current issues in child psychiatry. The latter half of the book is a bit of a potpourri; the chapters tend to be short and choppy, the topics are a little arbitrary and perhaps less "basic" to the field than those of the other volumes, but by and large they make interesting reading.

One danger in volumes of this sort is the tendency to overharsh editing, which reduces the contributions to dry, homogeneous synopses. This set of books, although tightly edited, is encyclopedic in scope but varied in style. For example, witness the freedom (and charm) allowed Robert Stoller in his chapter in volume 2 on gender disorders:

I shall approach my topic in an autobiographical tone; that should bring greater accuracy than an orderly, scholarly presentation. . . . With the optimism that probably sustains other researchers who persist on one subject, I always feel that today's concepts, theories, data, and conclusions are solid and pretty accurate—a pleasant, persistent illusion that keeps one going.

In sum, if a handbook is, as Webster defined it, "a compact reference on some subject," then Dr. Noshpitz' most alarming weakness is in the naming of this work. It is not a single book, and it is not compact. It is in fact approximately 15 pounds of books, clearly to be carried more by shelf than by hand. The point to emphasize, though, is that however misleading the name, the *Basic Handbook of Child Psychiatry* should stand as a basic reference on the shelf of any serious inquirer into the world of children.

DANIEL W. ROSENN, M.D.
Boston, Mass.

Disorders of the Schizophrenic Syndrome, *edited by Leopold Bellak, M.D. New York, N.Y., Basic Books, 1979, 629 pp., $27.50.*

The title of this massive tome is a misnomer and may mislead those unfamiliar with the three preceding volumes in Dr. Bellak's series of 10-year reviews of schizophrenia. His first review, *Dementia Praecox,* appeared in 1948; the second, *Schizophrenia: A Review of the Syndrome,* in 1958; the third, *The Schizophrenic Syndrome,* with Loeb as coeditor, in 1968. The four volumes cover nearly 50 years of developments in research and therapy in a field where breakthroughs always appear to be just over the horizon. Many of the contributors to the present work convey a feeling of muted optimism; although the answers are not quite at hand, they are expected in the next volume, or perhaps in the following one, which will fittingly appear in the year 2000, the start of the new millennium.

Manfred Bleuler contributes a foreword on his 60 years with schizophrenic patients, outlining very briefly his views on etiology and treatment. Dr. Bellak provides "An Idiosyncratic Overview" as an introduction and an epilogue on "What the Clinician Can Do Until the Scientist Comes." Bleuler and Bellak together represent 100 years of clinical experience with schizophrenic patients; their chapters should be read carefully because there are few others who have studied this illness so long or spoken so well about it.

Seven chapters deal with research. Torrey reviews the area of epidemiology, which, as he says, has so far contributed remarkably little but may be beginning to live up to its promise. Meltzer's chapter on biochemical studies is much more substantial and has nearly 700 references. This area has expanded tremendously in the past 10 years. The previous volume in the series did not mention dopamine, platelet monoamine oxidase, endorphins, viruses, Dr. Meltzer's own important work on neuromuscular dysfunction, or the neuroendocrine strategy. Dr. Meltzer concludes with the expectation that the next 10 or 20 years will lead to identification of the majority of the biochemical and neurophysiologic deficits, "providing research support is available at adequate rates." The other chapters on research are as excellent as one might expect from such experts as Cancro on genetic studies, Buchsbaum on neurophysiologic aspects (a chapter that shows the probable heterogeneity of the schizophrenic syndrome), Rabin on psychological functions, Rieder on children at risk, and Lyman Wynne on family studies.

The other major section has 10 chapters on clinical aspects. These are somewhat variable in scope, but for the most part the authors cover their assigned territory well. Carpenter and Strauss discuss diagnostic issues and also deal well with prognosis. Lipton and Burnett survey psychopharmacological treatment, which sadly has advanced little in the past decade. Max Fink reviews ECT and other somatic treatments, finding ECT to be the only one of value. Gunderson individually provides an excellent chapter on individual psychotherapy and joins Loren Mosher to review group, family, milieu, and community support systems. Zwerling writes on community psychiatric treatment, only slightly overlapping Mosher and Gunderson's chapter.

E. James Anthony contributes a short chapter on prevention, an area in which, unfortunately, there is not much to review. Paulina Kernbers provides a selective review on childhood schizophrenia and autism, concluding with the expectation that in the next decade diagnostic subgroups will be further clarified, leading to more effective early intervention and treatment.

Alan Stone contributes the final chapter on legal and ethical developments. Important legal cases have reduced the risk of involuntary confinement, shortened the length of hospitalization, and raised the questions of the right to treatment and the right to refuse treatment. Dr. Stone notes that these developments have made many state hospitals more dangerous and oppressive and led to schizophrenic patients wandering the city streets or living in welfare hotels, "the new back wards of this decade of legal progress."

Schizophrenia will be with us at least until Dr. Bellak's next volume, which we may fervently hope will contain more positive findings. In the meantime we must do what we can "until the scientist comes," although we may seem to be waiting for Godot (or the millennium).

A. ARTHUR SUGERMAN, M.D.
Trenton, N.J.

The Diagnosis and Treatment of Alcoholism, *edited by Jack H. Mendelson, M.D., and Nancy K. Mello, Ph.D. New York, N.Y., McGraw-Hill Book Co., 1979, 385 pp., $17.50.*

The flyleaf of this book promises that it is a definitive but readable "shot in the arm" for all who deal in the area of alcoholism. It is, indeed, comprehensive, but it challenges the reader to some initial aversive conditioning by beginning with a concoction of ill-mixed and confusing definitions and then moving on to an erudite but not necessarily easily swallowed section on anatomy, physiology, and biochemistry. The reader must start absorbing his alcohol almost immediately, with such intervening variables as microsomal ethanol oxidizing systems (MEOS). Once the reader survives these initial onslaughts, he or she is treated to a much "mellower" concoction of research and philosophy.

The best section of the book deals with the social settings and historical perspectives of alcoholism in the United States. This would have been a marvelous introduction to what is clearly a multifaceted approach to a multidimensional subject.

Several themes arise out of all this research. The first is that alcoholism is not a solitary or unidimensional problem and that any approach to alcohol as a problem, or the alcoholic as an individual, must be multifactorial in nature. All of the authors stress these philosophical approaches, whether they are discussing cross-cultural, genetic, or behavioristic elements of alcohol and the alcoholic.

The reader should not be lulled into thinking that this book is the "mixology" manual for the understanding or treatment of alcohol. What the reader will find, however, is a very sobering appraisal of alcoholism as a genetic, medical, biochemical, and social problem. The reader will also come to understand that there are a number of adequate but not definitive treatment methods—disulfiram, inpatient clinics, aversion and other behavior modification techniques—all of which have some specific effectiveness and also some specific limitations and drawbacks. All in all, this is a "fine brew" that with a slightly different mix in the blender could have been a "great brew."

ARON S. WOLF, M.D.
Anchorage, Alaska

Between Life and Death, *edited by Robert Kastenbaum, Ph.D. New York, N.Y., Springer Publishing Co., 1979, 184 pp., $15.50; $9.95 (paper).*

As a person who has spent a considerable amount of professional time working with dying patients, I have given a great deal of thought to the question of whether or not there is life after death. Having admired Elisabeth Kübler-Ross' work with dying patients and watching her evolving interest in and acceptance of the existence of life after death, I wondered whether my own prejudiced point of view would be challenged, supported, or left untouched by the data reported here. It also occurred to me that some of my colleagues working with dying patients seem to have become more philosophical, and I have to admit that working with dying patients has also affected me and my approach to life. It has caused me to think more seriously about establishing priorities.

Does everyone who works with dying patients change? Is the experience of approaching death or apparently dying and being revived so overwhelming that it leads one to reach for a way of expressing that incredible experience and to think of an existence beyond our present knowledge of life? Must we be involved in the world of parapsychology as soon as we approach this area because of the impossibility of using our customary vocabulary and imagery when we talk of death?

These and many other profound questions affected my attitude to reading Kastenbaum's book and certainly do not make me an objective reporter. I hold immense skepticism about a world beyond, but I also have a profound admiration for Dr. Kastenbaum's previous work, and I can report that this book is a sensible, balanced, and very interesting work. It sets the stage for much needed research in the field of investigating the experience of dying.

For the most part the book presents a range of thinking about the world of life beyond. It subjects the data to a sensible analysis leading to further research and possible hypotheses. It explores the phenomena reported by a variety of observers and patients who have approached clinical death and have been revived. The common denominator for all of these reports seems to be a healthy skepticism of anecdotal material, a call for much more critical analysis of experiences of death and the world beyond. The intriguing question of whether or not there is an afterlife has been answered by the response, "not yet proven." "Not yet" obviously implies "could be."

It appears to me that all of the reports of people hovering over their bodies during resuscitation or coming back to life after being pronounced dead can be explained by a human being's need to express this incredible experience in a vocabulary that is not equal to the experience. I feel that an analogous situation could be one of trying to find a way of verbally expressing love, orgasm, or panic. If one were to invite people who have had these experiences to express the feelings involved, they would all come up with a reasonably uniform set of phrases, images, and expressions. Chances are that if the person were French he would use a vocabulary or a set of images reflecting that cultural influence. If he were Mexican he would do the same but use a different set of images and analogies expressing that culture. The reports studied for this book show such cultural differences. Differences are also noted according to degree of education, sophistication, and age. I think, therefore, that extra-body experiences are explainable on the basis of expressions of unusual experiences.

Kastenbaum has put together a reasonably interesting book and one well worth reading for the serious student of emotions. The book is well written, well organized, valuable, and provocative. It is also eminently fair to the material and appeals to a sense of critical and rational thinking rather than to emotions, beliefs, or wishful thinking. I still do not believe in the afterlife, but I enjoy very much being intrigued by the possibility. I certainly would support further exploration of the subject in a serious fashion. Even if we do not find an afterlife, we will most certainly learn about our need for hope and for belief beyond ourselves.

Sexual Dysfunction: A Behavioural Approach to Causation, Assessment, and Treatment, *by Derek Jehu. New York, N.Y., John Wiley & Sons, 1979, 287 pp., $17.50 (paper).*

This short book is well organized and informative. It is easy to follow because each section and chapter is neatly divided with bold-faced headings and the paragraphs have subheadings. There are many tables, lists, and numbered sets of instructions.

This is the ideal book if one were preparing for an examination. It poses such questions as, What is the most common sexual dysfunction? What can cause sexual dysfunctions? What are the organic factors? What is the influence of previous learning experience? What may be accomplished during therapeutic interviews? What are the specific behavioral procedures in treating sexual dysfunction? It also provides the answers.

The book's value to the practitioner is more introductory than immediately useful. There is a clear, detailed bibliography with 81 specific references to Masters and Johnson and 33 to Helene Kaplan, neither of whom is considered a behaviorist by the author. I expect that anyone reading Derek Jehu's book would turn quickly to Masters and Johnson and

Kaplan if he or she had not already done so. Jehu's book is an excellent advertisement for others.

I found this book quite disturbing, not because of the author, who does a thoroughly competent review of his subject, organizes his material excellently, and writes well within the limits he sets for himself. It is the "behaviorist" approach to sex as he portrays it that is disturbing. It is too much like reading a book on how to repair a bicycle. There is the chapter on the 9 steps in changing a tire and the one on the 14 ways to adjust the gears. Where is mystery, joy, intimacy? There is more emotion in some books on the bicycle.

HARVEY BLUESTONE, M.D.
Bronx, N.Y.

Towards Understanding Relationships: European Monographs in Social Psychology 18, *by Robert A. Hinde; series editor, Henri Tajfel. London, Academic Press (Harcourt Brace Jovanovich), 1979, 359 pp., $36.50; $18.00 (paper).*

Relationships between people are universal, complex, integral, and intricate threads of life. Hinde's newest book meshes candor and a lively prose style as he tackles the study of relationships. He asserts that the book is not an attempt at systematic theory building. He painstakingly analyzes the pivotal concerns of issues and concepts in the quest for a comprehensive basis for describing and classifying dyadic relationships.

Part one, which contains three chapters, not only discusses the obstacles to a science of interpersonal relationships but critically highlights distinctions between the terms "personality" and "relationship." The author scrutinizes the dialectics involved in relationships, the vicissitudes of selective perception, cultural influences, the role of judgment, and the inherent nature, purpose, and limitations of the descriptive process.

Chapters 4–11 make up part two, which extrapolates principles underlying dissonance and balance theories and learning, exchange, and interdependence theories in relationship to content, diversity, qualities, frequency, and patterning of interactions. Validation of relationships in terms of similarity versus difference or reciprocity versus complementarity is made explicit through the use of family examples and extensive research findings. The distinction between deep and casual relationships is punctuated by a very thorough explication of intimacy, interpersonal perception, and commitment. Before concluding this section Hinde raises and answers in the negative a question crucial to the entire mission of the book, namely, "Are the categories of dimensions we have discussed concerned with phenomena at a level of analysis appropriate to the problems that those interested in the dynamics of relationships wish to solve?" (p. 139). He suggests, "Only future research can tell" (p. 140).

The dynamics of interpersonal relationships are the central focus of part three, chapters 12–20. The mutual influences of partners receives protracted attention with almost repetitive illustrations focusing on mother-child interactions. It would seem that this entire section could have been enhanced by reference to cross-cultural dyad relationships, particularly when the author goes to great length to articulate concepts of exchange, interdependence, reward, conflict, and power. The functioning and dysfunctioning brought about by change and stability, boundaries, systems, and subsystems evolves with clarity and valuable insights for personality theorists, social psychologists, and family therapists.

The concluding section of the book weaves factors of time, social pressure, personal constructs, and personality constructs into a terse consideration of development. Issues of initiating and responding carry a decisive message—relationships create identity and socialization patterns. Finally, Hinde debunks the notion that he has complete answers for understanding relationships. The limitations of his quest and the building blocks achieved in knowledge integration are underscored along with the reminder that "formidable obstacles remain to be overcome" (p. 326).

The extensive references, the well-placed diagrams and tables, the concise chapter summaries, and the author's finely attuned sensitivity, timing, and honesty make this a first-rate scholarly work. Although the book is intended primarily for advanced undergraduates, graduates, and research workers, it should appeal to helping professionals, personnel managers, and international agencies concerned with human development.

This Month's Reviewers

DONALD W. GOODWIN, M.D., is Professor and Chairman, Department of Psychiatry, Kansas University Medical School, Kansas City.

BENNETT SIMON, M.D., is Clinical Associate Professor of Psychiatry, Harvard Medical School at the Cambridge Hospital, Cambridge, Mass.

PETER REICH, M.D., is Chief of the Psychiatry Service, Affiliated Hospitals Center, Boston, Mass.

KLAUS MINDE, M.D., is Professor, Department of Psychiatry, University of Toronto, Ont., Canada.

HOWARD A. WINKLER, M.D., is in private practice in Tucson, Ariz.

MICHAEL SHEEHY, M.D., is Deputy Director, New York State Psychiatric Institute, New York, N.Y.

ELISSA P. BENEDEK, M.D., is Director of Training and Research, Center for Forensic Psychiatry, and Clinical Professor of Psychiatry, University of Michigan Medical Center, Ann Arbor.

RUSSELL NOYES, JR., M.D., is Professor of Psychiatry, University of Iowa College of Medicine, Iowa City.

STEVEN E. LOCKE, M.D., is Instructor in Psychiatry, Harvard Medical School, and Associate Director, Consultation/Liaison Service in Psychiatry, Beth Israel Hospital, Boston, Mass.

DANIEL W. ROSENN, M.D., is Director of the Department of Child Psychiatry, Beth Israel Hospital, Boston, Mass.

A. ARTHUR SUGERMAN, M.D., is Clinical Professor of Psychiatry, Rutgers Medical School, Piscataway, N.J., and Director of Medical Student Education, Carrier Foundation, Belle Mead, N.J.

ARON S. WOLF, M.D., is with the Langdon Psychiatric Clinic, Anchorage, Alaska, and is Associate Clinical Professor, University of Washington, Seattle.

SAMUEL KLAGSBRUN, M.D., is Medical Director, Four Winds Hospital, Katonah, N.Y.

HARVEY BLUESTONE, M.D., is Director, Department of Psychiatry, Bronx-Lebanon Hospital Center, and Associate Professor of Psychiatry, Albert Einstein College of Medicine, Bronx, N.Y.

MAUREEN MCCARTHY, PH.D., is a Postdoctoral Fellow, Department of Psychology, Florida State University, Tallahassee, Fla.

Books Received

This listing acknowledges the receipt of recent books. Books of particular interest to the readers of this journal will be reviewed as space permits, and copies will be sent to the publishers. Books cannot be returned to the publishers.

The Patient Speaks of Her Mother, 2nd ed., *by Harold A. Abramson, M.D. New York, N.Y., Vantage Press, 1980, 240 pp., $10.00.*

Psychoanalytic Treatment of Schizophrenic, Borderline, and Characterological Disorders, 2nd ed., *by L. Bryce Boyer, M.D., and Peter L. Giovacchini, M.D. New York, N.Y., Jason Aronson, 1980, 415 pp., $30.00.*

The Twenty-Year Phenomenon: Men and Women Talk About the Breakup of Their Long-Term Marriages, *by Jean Brody and Gail Beswick Osborne. New York, N.Y., Simon and Schuster, 1980, 283 pp., $11.95.*

Training of the Developmentally Handicapped Adult: A Practical Guide to Habilitation, *by Roy I. Brown, Ph.D., and E. Anne Hughson, M.Sc. Springfield, Ill., Charles C Thomas, 1980, 191 pp., $14.75.*

Treatment of Psychotic and Neurologically Impaired Children: A Systems Approach, *by David M. Brubakken, Ph.D., Judy A. Derouin, A.C.S.W., and Helen L. Morrison, M.D. New York, N.Y., Van Nostrand Reinhold Co., 1980, 260 pp., $17.50.*

Sexual Variance in Society and History, *by Vern L. Bullough. Chicago, Ill., University of Chicago Press, 1980, 692 pp., $9.95 (paper).*

Feeling Good: The New Mood Therapy, *by David D. Burns, M.D. New York, N.Y., William Morrow and Co., 1980, 385 pp., $12.95.*

Ethology and Nonverbal Communication in Mental Health: An Interdisciplinary Biopsychosocial Exploration, *edited by Samuel A. Corson and Elizabeth O'Leary Corson, with Joyce A. Alexander. Elmsford, N.Y., Pergamon Press, 1980, 268 pp., $41.00.*

Symbolism in Greek Mythology: Human Desire and Its Transformations, *by Paul Diel. Boulder, Colo., Shambhala, 1980, 218 pp., $12.50.*

Gay Is Not Good, *by Frank M. du Mas, Ph.D. Nashville, Tenn., Thomas Nelson, 1980, 320 pp., $11.95.*

Drug Abuse from the Family Perspective: Coping Is a Family Affair, *edited by Barbara Gray Ellis, M.S.S., M.P.H. Rockville, Md., National Institute on Drug Abuse, 1980, 140 pp., no price listed (paper).*

Toward a Definition of Clinical Social Work: Papers from the NASW Invitational Forum on Clinical Social Work, June 7–9, 1979, Denver, Colorado, *edited by Patricia L. Ewalt. Washington, D.C., National Association of Social Workers, 1980, 104 pp., $5.00 (paper).*

The Long Journey Home, *by Carol Ferland. New York, N.Y., Alfred A. Knopf, 1980, 294 pp., $10.95.*

National Drug/Alcohol Collaborative Project: Issues in Multiple Substance Abuse, *edited by Stephen E. Gardner, D.S.W. Rockville, Md., National Institute on Drug Abuse, 1980, 126 pp., no price listed (paper).*

Preventing Mental Illness: Efforts and Attitudes, *by Raymond M. Glasscote, M.A., and Eleanor Kohn, M.S.W., Allan Beigel, M.D., Merrill F. Raber, M.S.W., Nancy Roeske, M.D., Bonnie A. Cox, M.S.W., James B. Raybin, M.D., and Bernard L. Bloom, Ph.D. Washington, D.C., Joint Information Service of the American Psychiatric Association and the Mental Health Association, 1980, 138 pp., $10.00.*

Homosexual Desire, *by Guy Hocquenghem; translated by Daniella Dangoor. London, England, Allison & Busby (New York, N.Y., Schocken Books, distributor), 1980, 140 pp., $9.95; $5.95 (paper).*

Living with Schizophrenia: A Guide for Patients and Their Families, *by Alexander P. Hyde, M.D. Chicago, Ill., Contemporary Books, 1980, 128 pp., $8.95.*

Coping with the Crises in Your Life, *by Edgar N. Jackson, New York, N.Y., Jason Aronson, 1980, 210 pp., $15.00.*

How to Find a Job: A Woman's Handbook, *by Susan J. Jeffers, Ph.D., and Ellen F. Carr, M.B.A. New York, N.Y., Jeffers/Carr Associates, 1980, 62 pp., $2.95 (paper).*

New Perspectives in Abnormal Psychology, *edited by Alan E. Kazdin, Alan S. Bellack, and Michel Hersen. New York, N.Y., Oxford University Press, 1980, 563 pp., $18.95 (includes instructor's manual).*

Internal World and External Reality: Object Relations Theory Applied, *by Otto F. Kernberg, M.D. New York, N.Y., Jason Aronson, 1980, 348 pp., $27.50.*

Parents and Peers in Social Development, *by James Youniss. Chicago, Ill., University of Chicago Press, 1980, 295 pp., $23.00.*

Aging and Mental Disorders: Psychological Approaches to Assessment and Treatment, *by Steven H. Zarit. New York, N.Y., Free Press, 1980, 444 pp., $19.95.*

OFFICIAL ACTIONS

Report of the Secretary: Summary of Meetings of Board of Trustees and Executive Committee May 1979–April 1980

IT IS MY personal and Constitutional privilege as Secretary to report to the membership the actions taken by the Board over the past year. The report is arranged in alphabetical order according to topics; the items presented here do not include many matters that have been referred to appropriate components for further study and recommendation. As prescribed by our Constitution, especially important issues will be clarified at our Annual Meeting and a full report published in the *American Journal of Psychiatry* for permanent reference.

Beginning in June 1979, meetings originally scheduled as Executive Committee meetings were expanded to include the full Board. Thus, Area Trustees were present at each meeting throughout the year. They had greater continuity in their knowledge of issues being considered and are able to inform and be guided by their constituencies.

Many issues discussed by the Board over the past year related to capital and operating expenses and ensuring fiscal stability for the Association. An extraordinary meeting of the Board was held in October 1979 to discuss these issues and to prepare information and options which were presented to the Assembly at subsequent meetings. As recommended by the Assembly, the Board then acted to assess the membership for capital funds needed for the purchase of land for a new headquarters building, and also approved a 25% dues increase as well as a registration fee at the Annual Meeting to offset some of its costs. (A larger dues increase would have been necessary if this registration fee had not been established.) Assembly officers and members, as well as district branch presidents, assisted with an intensive educational campaign to inform the membership about these actions. The Board is extremely gratified with the initial response of the membership: approximately 52% of the members have paid more than $2.2 million toward the assessment. This has eliminated for the present a need to borrow money at high interest rates in order to finalize agreements with the developer. The Board has established an ad hoc committee to review individual requests to waive or reduce the assessment; the President, the Trustees, the Medical Director, and others are responding personally to a number of requests for additional information or to complaints. Your Treasurer's and other reports will contain more specific information about these fiscal issues.

This is an edited version of the report presented by the Secretary to the annual business meeting in San Francisco, Calif., May 5, 1980.

A consulting firm has been hired to assist in developing a long-range plan for the Association, and functional budgeting is being implemented this year. It is expected that these actions will help the Board to make sound fiscal decisions for the Association and will allow us to maintain and initiate programs of benefit to the membership.

The Board has acted on several matters of benefit to individual members, including a reduction in the rates for malpractice insurance for many members and improvements in the major medical plan for members and their families.

In the coming year there will be a focus on stimulating recruitment into the field of psychiatry and to membership in the Association.

I would remind you that every APA member is privileged to attend any session of components of the Association, except for meetings of the Ethics Committee or when a component is in executive session. Your strong support is appreciated; your recommendations for consideration by the Board or other components are most welcome.

The Board took the following actions.

ANNUAL MEETING

1. Voted to continue to present awards at the Convocation and to hold the business meeting and forum immediately after the opening session, beginning with the 1980 Annual Meeting (May '79).

2. Approved guidelines for holding meetings outside the continental United States (post-annual meetings) (June '79). In general, the guidelines noted the usefulness of promoting international exchange; suggested that post-annual meetings be held every other year, with some flexibility to accommodate to special locations or invitations; encouraged planning as far in advance as possible; noted the need for enough psychiatrists in the host country to assist in organizing the meeting; noted that cost factors should be considered, that such trips should have explicit professional and educational objectives, and that there is a direct line of staff responsibility regarding costs when joint meetings are held.

3. Approved charging a registration fee for members and guests attending the Annual Meeting to support much of the cost of these meetings; in turn, this would offset the amount needed for an increase in member dues (Sept. '79).

4. Approved a three-year trial of providing day care at Annual Meetings with the expectation that the program would become self-sustaining. Authorized $5,000 in the 1980 budget to support the program (Dec. '79).

5. Voted to schedule an extraordinary session at the 1980 Annual Meeting for a discussion of ERA and the relationship between mental health and equal rights; and approved the following statement to be read at the beginning of the opening session on Monday, May 5, and to be further publicized: "The American Psychiatric Association is on record as being in favor of 1) equal rights for women and 2) the Equal Rights Amendment. In an attempt to further these goals, the Board and the Assembly have endorsed the boycotting of states which have not ratified the ERA (by not holding Annual Meetings in these states). The recent membership referendum overturned the boycott policy. To address these issues, the American Psychiatric Association will hold an extraordinary meeting of the membership. . . . The Board urges your attendance" (May '80).

BUDGET/FISCAL

1. Voted to adopt a functional budgeting format, utilizing decision packages, effective 1981, to replace the existing exclusive departmental budgetary approach; authorized pilot projects in certain departments to be determined by the Medical Director, or on certain major decision issues, to utilize functional budgeting format during the remainder of the 1980 budget year; encouraged departments and components to include at least minimal decision packages in submitting budgets for 1980 (June '79).

2. Approved the 1980 budget of $8.8 million, which included income from a registration fee for members and guests attending the Annual Meeting to offset some of its cost, as well as a 25% dues increase (Dec. '79).

3. Approved a one-time assessment of the membership for capital funds to support purchase of land on which to build a new headquarters for the Association. Voted to proceed with plans for a Voluntary Fund Drive for additional capital funds for the building project (Oct. '79).

4. Established an Ad Hoc Committee to Review Requests to Reduce or Waive the Assessment and clarified policies regarding assessment and approved guidelines for waiver of the assessment (Feb. '80).

5. Established a Resource Development Committee to broaden the scope of present efforts to seek outside funding and to anticipate potential new programs and additional sources of funds.

6. Authorized the Joint Commission on Public Affairs to seek competitive bids from major publishers to produce a series of books on psychiatric topics of wide public interest. The publisher would produce and market the books and pay appropriate royalties to APA (Feb. '80).

7. Approved the following timetable for the annual budget process: 1) In April the Board shall establish a maximum ceiling on total expenditures, a maximum revenue to be realized by dues collection, and revenue requirements other than dues collection. 2) In September the Board shall approve major additions or deletions of programs. 3) In September the Board shall be provided with a report on progress and on any problems in meeting established limits. 4) At any regular meeting of the Board or its Executive Committee, the Medical Director or the Budget Committee may request a change in one or more of the established limits. 5) In December the Board shall review the annual budget to determine whether the limits established by the Board have been met.

CENTRAL OFFICE

1. In June, September, October, and December the Board heard reports from the Building Committee about the progress of plans to purchase land and enter into contractual arrangements with a developer to build a new headquarters building for the Association.

Authorized legal counsel to review and approve all documents related to this joint effort with the developer and to empower the Medical Director to act as Attorney-in-Fact to execute these documents on recommendation from legal counsel (Feb. '80).

2. Authorized construction of office space in the Museum Building and up to $7,000 from the Reserve for Future Expansion and Development to cover the cost; this new space will be used for staff support for the Annual Meetings.

3. Authorized disbursements from the Reserve for Future Expansion and Development account for capital improvements to the present Central Office buildings: $4,000 for purchase and installation of carpeting; $3,000 to install automatic temperature controls for night setback as required by law; and $6,175 to convert the furnace to gas rather than oil, which will result in significant savings in fuel costs (Sept. '79).

4. Approved in principle hiring a part-time, nonstaff APA member to serve as Editor of the *Hospital & Community Psychiatry* journal and adding six members to its Editorial Board (the Editor and the Board would then operate in a manner similar to the *American Journal of Psychiatry*) (Dec. '79).

5. Approved funding for a Deputy Editor for the *American Journal of Psychiatry* (Dec. '79) and appointed Dr. Morris A. Lipton to this position (Feb. '80).

COMPONENTS

1. A number of components were established, terminated, or transferred throughout the year: a) On May 17, 1979, the Ad Hoc Committee to Assist in Formulating Contingency Plans for the Results of the 1979 Election, the Ad Hoc Committee for the President's Commission on Mental Health, and the Ad Hoc Committee to Prepare the Board's Statement on Proposed (JCC) Amendments to the Constitution and By-Laws on the 1979 Ballot were terminated. The Ad Hoc Committees on Election Procedures, Implementation of the 1976 Referenda on Psychiatric Certification, Chronic Mental Patient, Civil Commitment, Long-Range Planning, and To Study the Council and Component Structure and Their Relationship to the Board and Assembly were continued. The Commission on Judicial Action (with staggered terms for members) and the Commission on Standards of Practice and Third-Party Payment were also continued for another five years. b) In June 1979, the Board established a new Council on Aging and approved charges for several of its task forces, which will seek outside funding to support much of their work. The final report of the Ad Hoc Committee on the 1976 Referenda on Certification was received at this meeting; its recommendations, together with those of the Council on Medical Education and Career Development, were transmitted to the American Board of Psychiatry and Neurology, publicized in *Psychiatric News*, and discussed by other components, including the Assembly; the ad hoc committee was discharged with thanks. A Committee for the Protection of Human Subjects in Psychiatric Research was

established within the Council on Research and Development, replacing a former task force on the topic.

Also in June the Council on Emerging Issues was terminated; a Committee on Emerging Issues was established within the Council on National Affairs. Components administratively housed within the former council were transferred to other councils. The Committee on Abuse and Misuse of Psychiatry in the United States was transferred to the Council on National Affairs; a new charge is being developed by the Council, and members have not yet been appointed. c) In September 1979, the Board established a Committee on Abuse and Misuse of Psychiatry and Psychiatrists within the Council on International Affairs and approved its charge. d) In December 1979, the Board established a Committee on Alcoholism and a Committee on State Hospitals within the Council on Mental Health Services. An Ad Hoc Committee to Review Requests to Waive or Reduce the Assessment was also established at this meeting. An Editorial Advisory Panel for *Psychiatric News* was established for one year; there will be liaison with the present Committee to Review *Psychiatric News*.

2. In September 1979, the Board asked all Councils and components to review their activities and determine if some programs or projects might be supported by outside funding.

3. The 1980 fall meetings of Councils and components were originally scheduled to be held in one hotel in Los Angeles. However, the Budget Committee found that at least $70,000 could be saved if these meetings were held on the East Coast. In December 1979, the Board voted to hold these meetings September 24–27, 1980, in Washington, D.C. The meetings will be accommodated in three hotels, and Central Office space will also be used.

4. The Ad Hoc Committee to Study Councils and Components recommended that the Reference Committee be reconstituted. The Assembly and the Reference Committee endorsed the concept of a new Joint Reference Committee (JRC). In December 1979, the Board approved the composition of the JRC to include the President-Elect as Chair, the Speaker-Elect as Vice Chair, two members from the Board and two members from the Assembly, and the Medical Director as voting members. Council chairs and appropriate commission chairs will report to the JRC and be ex officio members without vote. In February 1980, the Board approved an amendment to Chapter 6, Section 7 of the By-Laws (as prepared by the Committee on Constitution and By-Laws) to be on the 1981 ballot.

5. In June 1979, the Board authorized changing the name of a new Council to Council on Governmental Policy and Law. In December 1979, this Council stressed that additional staff (an attorney to draft legislation and regulations) was needed. In February 1980, the Board authorized funding of $17,500 from its Contingency Fund; Dr. Stone will contribute an additional $7,500 from his Presidential Fund to hire someone (perhaps a law student); the first effort will be development of a model commitment law.

6. *DSM-III*. a) In June 1979, the Board authorized publication of *DSM-III* and initially recommended that the classification system be implemented by January 1, 1980; however, when it was found in December that a longer period of time was necessary for individuals to receive the manual and be trained in its use, the Board voted to recommend that it be implemented no later than July 1, 1980. In September the Board approved guidelines for granting permission to reprint under the *DSM-III* copyright. The basic policy is restrictive; the Medical Director is authorized to grant permission to reprint segments but no major section may be reprinted, and the Diagnostic Classification may be reprinted on approval. The Board will approve any requests to translate the manual into other languages. In December 1979 the Board authorized the Council on National Affairs to develop a plan to translate the manual into Spanish. b) To help offset the cost of developing and printing *DSM-III*, the Board at several meetings considered ways to publish educational material related to the manual. An ad hoc committee of the Board was established in December to study these issues. On recommendation of this ad hoc committee, the Board voted in February 1980 to request that the President appoint an editor to review material written by several organizations, develop an introduction and outline, provide guidelines for using some of the present material or developing new chapters, discuss the problems with the representatives of the various contributing organizations, and report back to the Board.

A task force on educational programs was established within the Council on Medical Education and Career Development; conferences are planned. In September 1979, the Board authorized a working relationship between APA and Roche Laboratories, with Audio Visual Medical Marketing playing an intermediary/coordinating role to support educational conferences. The Board also authorized APA's cosponsorship with Columbia University of a course which was held in December in New York City.

7. In February 1980, the Board voted to have APA seek formal liaison with or representation on the ADAMHA/WHO committees for the development of *ICD-10* (which will relate to *DSM-IV*).

8. In December 1979, the Board authorized publishing the 7th edition of the Information Bulletin for Applicants, 1980 for accreditation in administrative psychiatry that includes a revised fee schedule: $300 is charged for the initial application, $150 to repeat one subject, and $200 to repeat two subjects.

9. In June 1979, the Board voted to hold meetings of the full Board in cases when Executive Committee meetings had been scheduled; thus all Areas are represented by their Trustees at all meetings during the pilot program of one year.

10. In December 1979, the Board approved the attendance of a representative of the Falk Fellows at meetings of the Board.

11. On recommendation of a Task Force on Directories, the Council on Internal Organization, and the Reference Committee, the Board approved publishing a single directory every two years (including some aspects of the *Biographical Directory* but reduced in size), with the understanding that the Board would review specifics of the categories to be included. This directory would be published in-house, with the expectation that it will produce more income than if published elsewhere.

12. In December 1979, the Board approved recommendations of the Task Force on the Impaired Physician which call for encouraging AMA and other organizations to establish policies ensuring psychiatric services for medical students; authorized the task force to develop a questionnaire to survey the district branches about methods of identifying and helping impaired physicians and to explore ways in which hospital and medical staffs can be encouraged to develop techniques for aiding impaired physicians. When problems and issues are clarified, the task force will develop informa-

tive resources such as a publication or video tapes. There will be collaboration with the American Hospital Association.

13. At several meetings the Board discussed issues related to projects providing peer review of psychiatric cases.

In June the Board was informed that the initial case review of CHAMPUS patients hospitalized over 180 days had begun following the endorsement of the project by the Assembly and the Board in May 1979. The Board approved the Assembly's recommendations that the current productive negotiations between APA and CHAMPUS continue to be pursued vigorously while a more acceptable balance between protection of privacy and need for accountability is achieved, and that these negotiations address themselves to concerns expressed by the district branches, committees, and individuals. It was reported at this meeting that CHAMPUS has agreed to no retroactive denial on inpatient care; there will be no retroactive review; patients and providers will be notified 14 days in advance of any action to deny benefits. Two Assembly liaisons were appointed to the Ad Hoc Committee on Health Insurance for Mental Disorders, which reviews this project and reports to the Board.

In April 1979, the Board authorized staff to explore a service that would provide Aetna with peer review of psychiatric cases covered by that company. In June the Board authorized the APA Office of Peer Review to proceed with the Aetna Psychiatric Peer Review Project for six months, at which time an analysis and report would be furnished to the appropriate components.

In September the Board received a report of the Ad Hoc Committee on Health Insurance for Mental Disorders and endorsed the Committee on Confidentiality's recommendation to request Aetna to return the mental health treatment form to the office of the attending physician after peer review has been accomplished; the Board reaffirmed its previous stance that APA will not enter into any new contracts at the national level until issues can be further clarified and voted not to extend the Aetna program beyond December 1979 without further evaluation. The Board indicated to the district branches that it will not interfere with local arrangements made with insurance carriers.

In December 1979, after hearing a detailed report from the Committee on Peer Review and recommendations from the Ad Hoc Commitee on Health Insurance for Mental Disorders, the Board authorized the APA Office of Peer Review to proceed with the APA/Aetna Project with the understanding that there will be careful monitoring by, and progress reports to, the Board and Assembly. Staff was authorized to respond to requests from other insurance companies to negotiate similar projects; these would need further action by the Board and review by the Assembly. The Board also acted on recommendations to be used in negotiations with third-party payers. The Board has continued to discuss how involved the APA should be in providing peer review and has asked staff to seek ways of providing indemnity and to explore the feasibility of establishing a separate corporation to handle peer review and related contracts.

15. The Board was advised in December 1979 that the Committee on Peer Review is revising the *Manual for Psychiatric Peer Review* and asked the committee to send first drafts to the district branches for comments by the branches' component on peer review.

16. In September 1979, the Board approved by-laws for a political action committee; the Assembly endorsed the Board's action in October; in December the Board approved a change in name to American Psychiatric Political Action Committee and approved the membership of its first board of directors, which will first meet in April 1980.

17. In December the Board approved guidelines for accepting financial support from pharmaceutical companies: APA will control the manner in which funds are spent and the content of any educational program and materials used in such a program; have responsibility for determining standards of taste and ethics for all aspects of programs receiving pharmaceutical support; and will acknowledge receipt of such support. A group of members and staff will meet with representatives of the pharmaceutical industry to discuss these guidelines during the 1980 Annual Meeting.

18. Approved entering into contractual arrangements with Mutual of New York for a re-insurance contract to extend psychiatric inpatient benefits of a lifetime maximum of $250,000; to extend the major medical plan to provide a supplement to Medicare; authorized a reduction in the life insurance premiums; and authorized a reduction in premiums for accidental death and dismemberment (Dec. '79).

19. Approved reduced rates to APA members as proposed by Chubb for professional liability insurance as of May 1, 1980; authorized the Ad Hoc Committee to Review APA's Professional Liability Insurance to continue negotiations with Chubb for even better rates and to investigate with other brokers the possibility of better plans for APA members (Dec. '79).

20. In April 1979, the Board was informed of the favorable decision in the Virginia suit, considered one of the most positive decisions for the practice of psychiatry in recent years. Because many local legal actions have a national impact, the Board voted to suggest to the district branches and Area Councils that, when anticipating litigation, the Commission on Judicial Action be asked to review the issue. (In September 1979, the Board was informed that the psychologists will appeal the Virginia case; the APA filed an amicus curiae brief in this appeal.)

21. In December 1979, the Board authorized a contribution of $8,000 to the California Psychiatric Society to assist with legal fees in Jamison v. Farabee, a right-to-refuse-treatment case in California.

22. On recommendation of the Commission on Judicial Action, the Board (June '79) authorized the Commission to participate in Project Release v. Prevost, a federal case that involves a full-scale effort to criminalize the New York commitment process; in December 1979, the Board authorized APA to file amicus briefs in Rennie v. Klein and Rogers v. Okin.

23. Authorized hiring the firm of Coopers and Lybrand as consultants to APA in preparing a long-range plan for the Association and established a component to work with the consultants (Dec. '79).

24. Authorized the Council on Medical Education and Career Development and the Office of Education to develop a plan for an audiovisual self-study program (for CME credits), derived in part from the content of the Annual Meetings, with the understanding that an outside contractor would be used for taping but that the program would be under APA control and ownership (Dec. '79).

25. In June 1979, the Board established an ad hoc committee to develop a position statement on patient package inserts; this ad hoc committee reviewed material developed by several other components. In September 1979, the Board

approved a position recommended by the ad hoc committee, contingent on approval by the Assembly. In October the Assembly revised a statement proposed by the Committee on Women to be compatible with the position approved by the Board in December and which will be published in the *American Journal of Psychiatry*.

26. In December 1979, the Board authorized publication of two task force reports: Task Force on Biofeedback and Task Force on Tardive Dyskinesia.

27. In December 1979, the Board approved a position statement on Teenage Parents and Their Children that includes suggested elements for effective programs.

28. In February 1980, the Board approved publication of the report of the Task Force on Alternative Patterns of Organization of State Governments to Provide Mental Health Services to Children and Adolescents and recommended that it be offered to the *Hospital & Community Psychiatry* journal for publication.

ELECTIONS

1. In June 1979, the Board referred the Area I action paper as approved by the Assembly to the Ad Hoc Committee on Election Procedures for revision of the section in the *Operations Manual* concerned with election procedures and campaign guidelines. In September the Board approved the new guidelines contingent on approval by the Assembly. In October the Assembly approved the election guidelines and their implementation in the 1980 election. In December 1979, the Board approved a revision in the *Operations Manual* that relates these new guidelines to operating policies.

2. Revised the *Operations Manual* to provide early appointment of the Nominating Committee, so that members could contact their Area representatives on the committee earlier in the process (Dec. '79).

3. In December 1979, the Board was notified of the receipt of a referendum on ERA and national meeting sites; signatures of more than 200 voting members had been verified; the referendum was on the 1980 ballot.

4. In December 1979, the Board approved two amendments to the Constitution and By-Laws regarding the composition of the Assembly (Chapter 7.1) and clarification of Chapter 8.6 assessments. In February 1980, the Board approved an amendment to Chapter 6.1 to change the composition of the Reference Committee. All of these amendments will be read to the membership at the Annual Meeting in 1980 and appear on the ballot in 1981.

ETHICS

1. Approved revising Section 9 of the *Principles of Medical Ethics with Annotations Especially Applicable to Psychiatry* as follows: "Ethical considerations in medical practice preclude the psychiatric evaluation of any adult charged with criminal acts, prior to access to, or availability of, legal counsel. The only exception is the rendering of care to the person for the sole purpose of medical treatment" (Sept. '79). (The Assembly approved this annotation in October 1979.)

2. Approved a revision to the *Operations Manual:* "When a member is under investigation for an ethical violation, he/she shall not be permitted to resign until all charges of unprofessional conduct have been resolved" (Sept. '79).

3. In December 1979, approved publication of a collation of the *Opinions of the Ethics Committee*.

INTERNATIONAL ACTIVITIES

1. Approved APA's joining with the Gerontological Society and the American Geriatric Society in endorsing the visit to the United States of a study group on diseases of the elderly from the People's Republic of China (Sept. '79).

2. Voted to publish the Report of the Committee to Visit South Africa in the *American Journal of Psychiatry* (June '79).

3. Sent a telegram to President Carter, the World Health Organization, and the United Nations deploring the situation in Cambodia and offering APA's assistance (Dec. '79).

4. Elected Dr. Semyon Gluzman, an imprisoned Soviet dissident, to Distinguished Fellowship (Dec. '79).

5. Throughout the year the Board heard plans for the Second Pacific Congress of Psychiatry, to be held after the Annual Meeting in May 1980, as well as for the Joint APA (Area II)/WPA Regional Symposium, to be held October 30–November 8, 1981, in New York City.

6. After the appearance of a *New York Times* article, sent a cablegram to Professor Snezhnevsky, Director of Psychiatry, Institute of Medical Sciences, U.S.S.R., asking for repudiation of an allegation that Academician Andrei D. Sakharov was threatened with "commitment to a psychiatric hospital" because of his political dissidence. The cable further stated that "we hope this report is in error since, if true, it would be taken as new evidence for the claim that there is political abuse of psychiatry in the Soviet Union."

LIAISON ACTIVITIES

1. Approved APA's becoming a participating organization of the Professional and Technical Advisory Committee for the Long-Term Care Program of the Joint Commission on Accreditation of Hospitals. In September 1979, the Board did not favor providing financial support for a new Accreditation Council on Mental Retardation since APA had accepted the JCAH invitation to serve on a Professional and Technical Advisory Committee for Services for Mentally Retarded and Other Developmentally Disabled Persons Program.

In December 1979, the Board endorsed the Assembly's recommendation that APA's representatives to the JCAH committee responsible for formulating the consolidated standards be instructed to inform the committee immediately that APA cannot accept these standards and that revised standards should be formulated.

In February 1980, the Board voted to instruct APA's representatives to the JCAH PTACs for the Hospital Accreditation Program, Psychiatric Facilities, and Long-Term Care to continue to insist that there be a provision for a medical staff in the accreditation standards for all psychiatric facilities, but that this provision would not preclude the organization of a clinical staff. It is the opinion of the APA Board that if there is no medical staff, a facility should not be considered a *psychiatric* facility; that institutions should be able to elect to have a medical staff if they wish to be accredited under the

standards for psychiatric facilities; and that if they do not wish to have a medical staff, they should be accredited under standards designed for other types of facilities. The Board also asked APA's representatives to the JCAH PTACs to report regularly to the Council on Mental Health Services.

2. Approved the establishment of formal liaison between the American Academy of Child Psychiatry and APA (May '79).

3. Authorized staff to cooperate with the United Mine Workers in a study of psychiatric disabilities following a mine accident (May '79).

4. Authorized staff to contract with Aetna and the United Auto Workers for a meeting to discuss chronic psychiatric disability.

5. Voted to submit only one nominee for each vacancy on the American Board of Psychiatry and Neurology (Dec. '79).

6. Voted to accept an invitation to organizational membership on the President's Committee on Employment of the Handicapped at no cost to APA, as recommended by the Committee on Rehabilitation (June '79).

7. Endorsed a resolution of the American Association for the Advancement of Science on science in-state programs (June '79).

8. Affirmed its policy that APA will not cosponsor meetings unless the Association is actively involved in the planning process and that such cosponsorship is usually limited to meetings of related organizations (June '79).

9. Supported the application of the American Board of Qualification in Electroencephalography to the American Board of Psychiatry and Neurology for establishment of special certification in EEG (June '79).

10. Asked the American Medical Association to reconsider its action to withdraw from the Liaison Committee on Continuing Medical Education and endorsed having one accrediting body for Continuing Medical Education (Sept. '79).

11. Approved storing the files of the National Commission on Confidentiality of Health Records at the APA Central Office and providing minimal staff support to the Commission (Sept. '79).

12. Strongly opposed HEW's approving the National Accreditation Association and American Examining Board of Psychoanalysis, Inc., as a nationally recognized accrediting organization (Sept. '79).

13. Endorsed comments on new regulations on day care (as prepared by the Council on Children, Adolescents and Their Families) and sent them to DHEW (Sept. '79).

14. Approved joining with other major organizations to honor Mr. Norman Lourie on his retirement as Secretary of Welfare for the State of Pennsylvania (Sept. '79).

15. In December 1979, the Board authorized the Committee on Medical Education to develop programs and materials related to recruitment of medical students in collaboration with the American Medical Students Association; official liaison with AMSA will be through the APA committee.

16. Approved liaison with the American Academy of Family Physicians, the American Academy of Pediatrics, and the American College of Physicians (Dec. '79).

17. Approved in principle a working document, "Psychiatry in Training for Primary Care Specialties," to be used in further discussion with the American Academy of Family Physicians and the American College of Physicians, and authorized the Committee on Psychiatry and Primary Care Education to collaborate with representatives of these organizations to develop a final document (Dec. '79).

18. Voted to suggest to the Residency Review Committee, the American Association of Directors of Residency Training Programs, and the American Association of Chairmen of Departments of Psychiatry that each residency program develop a written procedure to be followed when checking the credentials of residents requesting transfer; and further, that the RRC consider including this requirement for procedures (without defining them specifically) in the *Essentials and Guide for Psychiatry Residency Training Programs* (Dec. '79).

19. Endorsed a document prepared by the National Cancer Institute, "Coping with Cancer: A Guide for the Health Professional," at no cost to the Association (Dec. '79). (This is part of a larger NCI program to provide information on the psychosocial aspects of cancer to patients and their families, both directly and through health professionals.)

20. Approved APA's having organizational membership on the U.S. Council for the International Year of the Disabled (1981) (Dec. '79).

21. Authorized collaboration with the AMA in producing a *Mini CPT-IV* for psychiatrists (Dec. '79).

22. Approved guidelines prepared by the Section Council on Psychiatry regarding appointments to the Section Council and APA's delegates to the AMA House of Delegates (Dec. '79).

23. Approved APA's becoming a member of the Federation of Organizations for Professional Women, with dues of $200 per year. The locus for the activity and liaison will be the Committee on Women, with Dr. Spurlock attending the meetings which are held in Washington, D.C.

24. Endorsed the American Electroencephalographic Society Guidelines for EEG as recommended by the Councils on Medical Education and Research and Development (Feb. '80).

25. The Council of Medical Specialty Societies needed to increase dues to support ongoing programs and increased activities. In February 1980, the Board approved an increase in APA's dues from $1.75 to $1.85 per voting APA member. APA's representatives have organizational responsibilities on CMSS.

26. Approved APA's cosponsoring sessions at the 1981 AMA Winter Scientific Meeting at no cost to APA. Dr. Shervert Frazier, a member of the AMA Council on Continuing Physican Education, will be responsible for program development in concert with APA staff Dr. Henry Work and Ms. Carol Davis.

27. Approved APA's cosponsorship of a National Institute for Long-Term Care, which is tentatively scheduled for September 26-27, 1980, in Washington, D.C.

MEMBERSHIP

1. On recommendation of the Assembly and the Membership Committee, approved allowing a grace period of at least one year before any member who has not complied with Continuing Medical Education requirements is dropped (Dec. '79).

2. Supported having the Membership Committee hold workshops to educate the district branches about Fellowship procedures at the Annual Meetings, orientation sessions for district branch presidents-elect, and perhaps a presentation to the Assembly, rather than holding regional workshops (Dec. '79).

3. Approved criteria guidelines for consideration of potential APA member benefit programs (Dec. '79).

4. In the 1979 election, members voted to increase the requirement as General Member from 5 to 8 years to be eligible for consideration for Fellowship. In February 1980, the Board voted a one-year phase-in implementation of this amendment. For the 1980 nomination process, members with six or more years as General Member will be eligible for consideration as Fellowship nominees, including those who had already been nominated by their branch.

5. Considered routine membership matters at each meeting and took some or all of the following kinds of actions: authorized dropping from APA membership those members who had resigned from or been dropped by their district branches for nonpayment of dues; authorized administrative reinstatement of those members who paid their dues arrearages and returned to good standing in both the branch and the national Association; approved transfers and acceptances or denied them if circumstances indicated; accepted applications and resignations; granted dues waivers when warranted, or Inactive member status; approved membership status changes from one category to another; acted on recommendations for Distinguished or Honorary Fellows (May, June, Sept., Dec. '79; Feb., April '80).

H. KEITH H. BRODIE, M.D.

Report of the Treasurer

General. This report is prepared from audited figures for the fiscal year which ended December 31, 1979. Data presented also appear in the auditor's annual report. A statement of financial condition is shown in table 1, and table 2 reflects revenues and costs for the year. This report, together with the tables, will provide the membership with the information they need to assess the operation and financial condition of the Association. In the interest of complete and accurate reporting of fiscal information, all assessment receipts, as well as the investment of such receipts, have been accounted for separately. Therefore, table 1 includes a new fund designation, the Building Fund, which displays the assets and liabilities associated with the assessment and fund drive.

Fiscal status. Execution of the fiscal year 1979 budget resulted in income of $8,635,808 (1/2 percent below the budget estimate) compared with expenses of $8,585,215 (1 percent below budgeted expenditures). This resulted in a net surplus from general fund operations amounting to $50,593. The surplus of income over expenses for 1979 basically stems from teamwork among APA policy makers and staff to overcome obstacles posed by inflation and recession through bolstering income and minimizing expenses. Income was strengthened by *DSM-III* sales of $560,000, revenues from Continuing Medical Education courses offered during the annual meeting that exceeded budgetary estimates, a strong grant/contract program that produced outside support in excess of $1,300,000 for needed programs, and increases in rate schedules for the products and services provided by APA to the public. Expenses were controlled during 1979 by the successful efforts of component chairs and department heads to keep expenditures within budget allocations and specific cost containment efforts by the leadership and staff, including the elimination of three existing positions during the year.

Investments. The stated investment policy of the Association is to "employ sound investment vehicles affording the maximum return consonant with safety of capital, i.e., the type of investment a prudent individual would seek." With this in mind, safety of capital has been identified as the first objective of the investment program.

Total investment income for the year amounted to $200,943. Of this amount, $23,053 stemmed from savings and loan certificates (reflected in cash and equivalents in table 1). Earnings from U.S. Treasury bills, short-term bonds, and short-term commercial bank certificates of deposit amounted to $67,017. These investments represent the general fund working capital of the Association and are invested in accordance with requirements in the annual cash budget. Balances ranged from a high of $1,200,000 in midyear to a low of $150,000 at year end. This experience reflected an orderly execution of the cash budget and maximum return on short-term holdings within the conservative bounds established by fiscal policy.

Pursuant to the sale of the Connecticut Avenue and Hillyer Place properties for $1,120,000, APA received 9% notes receivable from the buyer in the amount of $1,070,000 on February 28, 1979. During the year the Association received payments on the balance in the amount of $200,000. The outstanding balance as of December 31, 1979, was $870,000. Interest income on these notes for the year was $69,719.

APA was fortunate during 1979 with respect to the equities portion of its portfolio. Total fund return on equities during the year amounted to 23.7% as compared with 10.4% for the Dow-Jones Industrial Average and 18.4% for the Standard & Poor "500." The total fund investment return on the overall portfolio since late 1975 (the time of the formation of the Investment Advisory Committee) has been 41.5 percent.

The quality of the equities portion of the portfolio has improved markedly since the inception of the Investment Advisory Committee. The committee inherited a stock portfolio in which the original cost of securities was greater than the corresponding market value. The committee has continually worked to achieve an appreciation of securities, with minimum risk, in order to bring the market value of securities above the historical costs. The committee's steady performance led to the achievement of this goal as of Dec. 31, 1979.

Status of reserves. The Association averted the need for an increase in member dues during 1978 and 1979 by utilizing surplus funds realized during 1976 and 1977. In February 1977 the Executive Committee of the Board of Trustees approved the establishment of the Reserve for Stabilization of Member Dues. The purpose of this action was to develop a reserve account from which sufficient funds could be transferred to operating income for each of three years (1977, 1978, and 1979) in order to meet pressures for increases in operating expenses and thus preclude the need for a dues increase until 1980. At the time this reserve account was established, APA anticipated that an extremely high level of surplus funds would be generated from operations during 1976 and possibly during 1977. This expectation was based largely on the Board's intention to change its fiscal year from April–March to a calendar-year basis, effective January 1, 1977. The surplus of income over expenses for 1976 amounted to $833,704. A portion of this surplus ($579,075) was placed in the Reserve for Stabilization of Member Dues and the remainder was allocated to the Reserve for Future Expansion and Development ($254,629).

An additional surplus of $507,302 was realized from 1977 operations. Of this amount, $279,650 was placed in the Reserve for Stabilization of Member Dues, $225,371 went to the Reserve for Future Expansion and Development, and $2,281 was placed in Unrestricted Surplus. As of December 1, 1978, the balances of these three reserve accounts were as follows: Reserve for Stabilization of Member Dues, $316,512; Reserve for Future Expansion and Development, $1,980,000; and Unrestricted Surplus, $260,009.

This is an edited version of the report presented by the Treasurer to the annual business meeting in San Francisco, Calif., May 5, 1980.

TABLE 1
Comparison of Fiscal Years 1978 and 1979

Item	1978	1979
ASSETS		
General fund		
Cash and equivalents	$ 335,000	$ 268,291
Accounts receivable	652,182	616,015
Accrued interest receivable	7,711	6,004
Deferred charges and prepaid expenses	217,342	261,933
Marketable securities		
Stocks and bonds at cost (market value $504,036)	—	501,990
Stocks and bonds at quoted market value	488,394	—
U.S. Treasury Bills at cost	311,926	133,250
Due from Building fund	—	120,467
Notes and advances receivable from APMA[a]	1,757,085	1,757,085
Less valuation reserve	(1,757,085)	(1,757,085)
Notes receivable, sale of property	—	870,000
Land and building, Central Office, at nominal value	1	1
Furniture and equipment, Central Office, at nominal value	1	1
Land and building, new headquarters, at cost	1,113,886	—
Deduct		
Cash and marketable securities allocated to restricted fund	(305,189)	(285,881)
Total general fund	2,821,254	2,492,071
Building fund		
Cash and equivalents	—	$ 31,709
Accrued interest receivable	—	5,907
Deferred charges and prepaid expenses	—	120,467
Marketable securities		
Repurchase agreements held at bank at cost	—	1,250,000
U.S. Treasury Bills at cost	—	97,775
Total building fund	—	1,505,858
Restricted fund		
Cash and marketable securities allocated from general fund	305,189	285,881
Total restricted fund	305,189	285,881
Total assets	3,126,443	4,283,810
LIABILITIES		
General fund		
Accounts payable and accrued expenses	270,965	442,920
Due to district branches	31,014	1,119
Deferred income	5,125	51,361
Reserve for Stabilization of Future Dues	607,039	—
Reserve for Future Expansion and Development	1,689,473	1,682,473
Less valuation reserve, marketable securities	(45,967)	—
Unrestricted surplus		
At beginning of year	260,009	263,605
Net change during year ended	3,596	50,593
At end of year	263,605	314,198
Total general fund	2,821,254	2,492,071
Building fund		
Due to general fund	—	120,467
Deferred credits, building fund receipts	—	—
Assessment payments received	—	1,347,775
Voluntary fund drive receipts, less expenses	—	31,709
Interest earned	—	5,907
Total building fund	—	1,505,858
Restricted funds		
Principle balances of restricted funds	305,189	285,881
Total restricted funds	305,189	285,881
Total liabilities	3,126,443	4,283,810

[a]American Psychiatric Museum Association, Inc.

Although the Reserve for Stabilization of Member Dues contained $316,512 in early December 1978, an amount of $607,039 from this source was needed for transfer into income for 1979 operations in order to balance the budget. Had this fact been anticipated in earlier years, a larger amount of the surplus funds generated from 1976 and 1977 operations could have been placed into the Reserve for Stabilization of Member Dues at that time. Therefore, the Board of Trustees, during its December 9–10, 1978, meeting, approved the transfer of $290,527 from the Reserve for Future Expansion and Development to the Reserve for Stabilization of Member Dues, which brought the total of that reserve account to $607,039. The Board further approved that this total amount of $607,039 be transferred from the Reserve for Stabilization of Member Dues into operating income for 1979, which increased projected income to the level of anticipated expenses and balanced the 1979 budget. The resulting balances of reserve accounts as of December 31, 1978, were as fol-

Governance (Board of Trustees, Councils, Assembly)	17.54	18.86
Publications (APA journals and book sales)	36.27	33.99
Public Affairs (public information and government relations)	7.72	8.04
Member services (membership services and educational programs)	28.16	28.15
General and administrative (administrative offices and other costs)	10.31	10.96
Total dollars	$7,573,446	$8,535,215

lows: Reserve for Stabilization of Member Dues, $607,039; Reserve for Future Expansion and Development, $1,689,473; and Unrestricted Surplus, $263,605.

During 1979 the balance of the Reserve for Stabilization of Member Dues ($607,039) was utilized as income to preclude the need for a dues increase during that year, in accordance with the plan developed by the Board of Trustees in February 1977. The Reserve for Future Expansion and Development was reduced by $7,000 during 1979 (from $1,689,473 to $1,682,473) due to special funding for two policy components. The Unrestricted Surplus increased by $50,593 during 1979 because of the surplus from general fund operations. The balances of the reserve accounts as of Dec. 31, 1979, were as follows: Reserve for Future Expansion and Development, $1,682,473; Unrestricted Surplus, $314,198.

Publications. The Association maintains approximately 90 book titles in inventory. Total revenues for 1979, net of discounts, were $805,370. This represents an increase of $532,175 over 1978 sales of $273,195. The increase basically stems from sales of *DSM-III* during the last quarter of 1979 amounting to $560,000. Revenues from the initial sales of *DSM-III* helped support overall expenses of APA during 1979. Publication sales usually amount to about $250,000, for a slight excess of revenue over expenses, which keeps the activity on a self-sustaining basis.

Psychiatric News generated revenues of $1,280,469, contrasted with expenses of $1,045,315, for a surplus of $235,154. The revenue amount represents an increase of $45,090 over 1978 totals. The *American Journal of Psychiatry* produced revenues of $1,192,595 and incurred expenses of $1,207,736, for a deficit of $15,141. It should be noted that the Association levies an overhead charge to its three publications at the rate established for indirect costs for federal grants and contracts. The overhead rate for the *American Journal of Psychiatry* during 1979 was 36.1% of direct costs. This publication shows a surplus of $305,135, excluding APA overhead charges. The *Hospital & Community Psychiatry* journal realized revenues amounting to $259,187 and expenses of $476,625. The resulting deficit was $177,438. After adjusting for the APA overhead charge to the journal, the deficit for 1979 is reduced to $50,015.

Grants and contracts. In February 1977, the Association began working to increase its level of support from grants and contracts. Since that time, income from these sources has increased from $294,842 per year to an annual rate of $1,374,178. These additional funds have enabled APA to provide needed products and services without placing an additional burden on other income sources. The Association is establishing a Resource Development Committee, which will endeavor to generate additional grant/contract funds to support the provision of products and services to members and their patients.

Conclusion. It is a pleasure to present to you what I believe is a very forthright and positive annual report on the fiscal activities of the APA during 1979 and the financial condition of the Association at this time. You are welcome to discuss any aspect of this report with me during the annual meeting or to review the total audited figures for income and expenses at APA headquarters.

I wish to express my gratitude to you for entrusting me with the responsibility for the fiscal affairs of the APA, and to the Assembly, to the Board of Trustees, to the officers, and to the Investment Advisory Committee for their support and their ongoing interest in the financial stability of the Association. Appreciation is also due to the Medical Director, the Deputy Director for Business Administration, the Comptroller, and the entire staff for their capable assistance whenever needed during the year.

CHARLES B. WILKINSON, M.D.

Report of the Medical Director

I AM PLEASED to present my annual report to each of you, the first in the new decade—the 1980s. Although I will follow my usual pattern of highlighting staff activities and developments, I would also like to use this occasion to make a few additional comments and observations.

One of my hopes for this new decade is a wider perception among members of APA's strengths and capacities as well as a realistic evaluation of the problems facing our patients and our profession. Whenever I have an opportunity to visit district branches throughout the country, I make a point of focusing on this theme. In this context I have attempted to deal with some of our members' episodic moods of doom and gloom about the future of psychiatry. This syndrome is characterized by the belief in certain myths which, in my judgment, can lead to errors in policies and actions. The first is the myth that the profession is under severe siege and is cut off from allies. The reality is that we have many problems and there are areas where we must struggle very hard. However, from my perspective, it is a serious error to underestimate the many friends and potential allies that psychiatry has—in the general public, the medical profession, the courts, the legislative and executive branches of government, the clergy, and mental health professionals. We must be careful to differentiate the irrational and malignant antipsychiatry groups from those who have indicated a willingness or demonstrated a potential to discuss issues with us in a serious manner, even if some of these groups do criticize us from time to time. Unless we do this, our policies can rigidify, we can alienate genuine friends, and the profession will develop a momentum toward self-fulfilling negative prophecies.

Of course there are very serious challenges facing us in the years ahead, but in my view a strongly functioning APA can and will deal with these problems—with vigor, intelligence, and persistence.

A second myth that we should lay to rest is the perception of psychiatry as mired in a perpetual identity crisis. From my vantage point, we underwent several shifts in direction during the 1960s and 1970s. My travels to many district branches, however, have convinced me that a consensus has evolved during the last few years. We have emerged from a period of flux and rapid change with a much clearer medical identity. This identity involves strong alliances with the rest of medicine and also recognizes our fundamental role as physicians. Such a model is not one of biological reductionism, but gives strong emphasis to the psychological, the social, including epidemiological, and other salient variables directly related to psychopathology and its treatment. Of course, debate continues on the precise role of psychosocial variables and we have occasional passionate differences over the psychiatric implications of major social policies. Nevertheless, my reading of the membership is that the ideological differences among us diminished significantly during the late 1970s. It is time to state forcefully that the identity crisis is over.

This is an edited version of the report presented by the Medical Director to the annual business meeting in San Francisco, Calif., May 5, 1980.

In the light of our need to be strong in order to cope with the many challenges that will face us in the '80s, I believe it would be a tragic mistake to pull up the wagons and retreat into a constricted reactive posture. We must clarify the priorities, objectives, and functions of the profession and the Association and then choose wisely among them.

My staff and I have been deeply influenced in the past six months by the variety of fiscal issues facing the Association: the levying of the assessment to finance a new headquarters building, the dues increase, and the unprecedented imposition of a registration fee for members attending the annual meeting.

In particular, the assessment and dues increase were lightning rods that brought to our attention many issues in addition to the manifest fiscal questions. The image that the Association projects to its members is extremely important and we must take a close look at what the benefits of membership really are. I have read every letter protesting the assessment. More than that, I have looked at every scrawled note on the bill itself. I didn't know that several of our members were descended from Samuel Adams and identified with those who put on a famous tea party. Of course, many of our members were traumatized by the assessment and the dues increase, as indeed were the Assembly and the Board last fall. Nevertheless, I have been delighted with the magnificent response so far to the assessment and the dues increase. I have also been pleased that the number of resignations is not unusual for this stage of our fiscal year. The opportunity to engage in a dialogue with members who have protested the fiscal decisions has been a rewarding challenge for me. Many of you have also been engaged in this process and I urge you to increase your activities. Concerned and responsive leadership will make a real difference.

During the past six months an interdepartmental staff committee, consisting of the Medical Director; Carol Davis, Special Assistant to the Medical Director; Dr. Lee Gurel, Director of Membership Services and Studies; Mary Jane Merrick, Chief of Data Processing; Marta DeLalla, Membership Associate; Ron McMillen, Assistant Director of Public Affairs; Dr. Jack White, Deputy Director for Business Administration; and Robert Milanicz, Comptroller, have met regularly to monitor the assessment and the dues billing. This has involved planning responses to the inquiries and questions that have come from our members about the assessment and dues increase; working with the Ad Hoc Committee to Consider Waivers of the Assessment so that guidelines could be established; ensuring that all appropriate data about the assessment waivers and the dues were entered into the computer; and reviewing data to determine the percentage of members who had paid the assessment and dues to consider what appropriate actions might be if the cash flow for the Association was not maintaining 1979 levels. This has indeed consumed a great deal of staff time. However, we have responded to every inquiry from a member and attempted to ensure that the members are aware of the benefits of belonging to APA. We have been successful, in several instances, in persuading a member to pay the assessment and dues and not resign from the Association.

When you return home from this meeting, an all-member

mailing will be delivered. It will contain routine items like submission forms for next year's annual meeting, and we have also included a brief newsletter, "APA Is Working For You," highlighting membership benefits and activities; a Quick Reference Telephone Directory for locating specific staff who can help with various problems; and information about public affairs activities and media resource details, among other things. The Association is active in many areas that touch every member's practice, and it is important that we communicate this clearly and concisely. Many of our members feel isolated or apart from APA and each of us has an obligation to reduce this distance.

As I have stated on a number of occasions, we must have priorities because we can no longer attempt to do a little bit of everything. Fiscal restraints must be recognized and choices among alternatives made. With the institution of long-range planning and functional budgeting, I believe that we will make these hard choices and that our objectives and functions will be clearer.

I believe each of you will enjoy this annual meeting, our 133rd. Not only is San Francisco a pleasant place to be, but the program content is exceptionally rich and exciting. There will be extensive press coverage of the meeting and of events surrounding it. I am convinced that the scientific coverage will be beneficial for psychiatry. My personal thanks goes to Dr. Allan Beigel and the Scientific Program Committee for their continued commitment to excellence.

Each of you also has my special thanks for your support of our staff. President Stone, Speaker Pasnau, and other APA leaders have been extremely positive in their support of our strong and effective staff, and I am most appreciative of their actions demonstrating their intent in this matter.

I am pleased that I have been asked to continue as your Medical Director. With full recognition that I am clearly accountable to the Board of Trustees, to the Assembly, and to the membership, I will continue as your Medical Director with the belief that I am living up to my own standards and your expectations.

The remainder of my report deals with more specific staff activities. For historical purposes, the Medical Director has asked each department and division head, as well as each deputy director, to prepare detailed reports, which are appended.

MEDICAL DIRECTOR'S OFFICE

Several additional activities have been assumed by our office during the past year to improve coordination of particular functions.

My office has assumed responsibility for monitoring all of APA's liaison activities with other organizations and preparing a special report for each meeting of the Board of Trustees on these activities. We currently have official liaison representatives to more than 30 organizations, and the APA President very often appoints ad hoc representatives to attend meetings deemed to be of interest to the Association. All of these representatives submit reports and recommendations to the Trustees. My office ensures that all suggestions and action items are transmitted to the appropriate people and that effective action is taken.

I have recently transferred to my office the monitoring of all of APA's international affairs activities, including staff support for the Council on International Affairs. Many of our members are increasingly interested in transcultural psychiatry and in relationships with colleagues in other countries. We are actively working to establish an efficient and organized data base for these activities.

One example of such activities this past year, in addition to those mentioned in the annual report of the Council on International Affairs, was helping the Embassy of the Peoples' Republic of China to coordinate the schedule of a visiting team of Chinese neurologists and internists who were here in the United States studying the diseases of the elderly. This type of activity broadens our colleagueship with physicians and specialists from other countries.

The Office of the Scientific Program and its staff have been transferred to the Office of the Medical Director, and we are now closely involved in the preparation and production of the program and syllabus for the Annual Meeting.

Dr. Donald W. Hammersley, Deputy Medical Director, Ms. Claudia Hart, his administrative assistant, and Ms. Dottie Myrick, his secretary, serve as a part of the Medical Director's Office and provide assistance in implementing policies of the Board. They also provide valuable staff support to various APA components. Dr. Hammersley has the administrative responsibility for several departments in the Central Office (the APA CHAMPUS Peer Review Project, Membership Services and Studies, Library and Museum), is Editor of *Hospital & Community Psychiatry* and Director of the Hospital and Community Psychiatry Service, and provides primary staff support to a number of organizational components, including the Commission on Standards of Practice and Third-Party Payment, the Ad Hoc Committee on Interprofessional Relations, and the Ad Hoc Committee on Health Insurance for Mental Disorders.

GENERAL COUNSEL

APA general counsel, Rogovin, Stern & Huge, under the direction of Mr. Joel Klein, has been very active this past year in a variety of areas of legal concern to the Association. As various courts and agencies seek to expand the application of the antitrust laws to medicine, APA's interest and responsibility in these matters has heightened. Last year I reported to you on work done in the case involving the Virginia Neuropsychiatric Society; clinical psychologists sued two Blue Shield programs and the district branch, alleging a conspiracy to deny direct reimbursement for psychologists. Rogovin, Stern & Huge represented the district branch and a successful result was achieved at trial. The court found no conspiracy and stated that clinical psychologists require medical supervision. The case is currently being appealed. Similar issues have been raised in a suit filed by the Ohio Attorney General, charging the Joint Commission on Accreditation of Hospitals with violating the antitrust laws by failing to grant psychologists full admitting and clinical privileges. The Ohio Psychiatric Association and the Ohio Medical Association have been charged as coconspirators with JCAH. Mr. Klein is monitoring these matters very closely as well as developments in the FTC suit against the AMA, which places serious restrictions on the right of medical societies to restrict advertising.

Another area that required a significant amount of time was developing and negotiating the contract for APA's new headquarters building in downtown Washington. This project has been brought to a successful conclusion and involved

major tax and real estate issues, as well as delicate negotiations with a major Washington developer. Dr. John McGrath, Chair of the APA Building Committee, and Dr. Jack White, Deputy Director for Business Administration, worked closely with Mr. Klein on this.

OFFICE OF BUSINESS ADMINISTRATION

Under the very capable direction of Dr. Jack W. White, Deputy Director for Business Administration, this office has completed its first five years. Highlights of the office's activities during this period have included preparation and execution of balanced budgets for each of the past five years, establishment and maintenance of a strong control mechanism for management of the Association's investment portfolio, continued reorganization and refinement of the business functions, implementation and monitoring of a new personnel classification system, and fiscal issues complicated by deterioration of the overall economy, by the proposed dues increase for 1980, the initiation of an annual meeting registration fee for members, and the financing of a new headquarters building.

I would particularly call your attention to Dr. White's report on the 1981 budgeting process and implementation of a functional budgeting system. Functional budgeting will allow the Association to achieve its objectives by assigning resources to accomplish those objectives and will ensure control of expenses as the budget is executed. Functional budgeting will lead to the development of improved fiscal policies as well as serve as a means to control costs.

Dr. White is to be particularly congratulated for helping to ensure that the Association found suitable space for a new building and that the fiscal arrangements were favorable to APA.

OFFICE OF EDUCATION

This office, under the capable direction of Dr. Carolyn B. Robinowitz, Deputy Medical Director, provides the management skills as well as the expertise in a variety of educational endeavors now under the aegis of APA. For example, this office worked with the committee that developed the fourth Psychiatric Knowledge and Skills Self-Assessment Program, which allows APA members to test their performance on an examination against a group of their peers and provides up to 40 hours of Category I CME credit. More than 5,700 APA members have chosen to participate in this important continuing education activity.

During 1979, in collaboration with a consortium of psychiatric educational service organizations, the Office of Education held several conferences to help psychiatric educators improve their teaching activities and skills. This project, through a grant from NIMH, provides specific information to assist educators in areas such as selection and use of assessment technique and methodologies, patient management problems, work habits, professional attitudes, etc.

Another major activity of the office during the year was planning the Conference on Psychiatric Manpower and Recruitment, held in March 1980 in collaboration with representatives of a consortium of psychiatric education and service organizations under an NIMH grant. More than 140 participants considered issues of psychiatric manpower, distribution, and utilization as well as recruitment. Both the quantity and the quality of the participants attested to the intense interest in this problem. The meeting will result in a report, including far-reaching recommendations to attack the recruitment problem on many levels. It is the first major step in what we know will be a long-term process.

APA also collaborated with the American Medical Student Association and the American Association of Directors of Psychiatric Residency Training in developing a brochure that describes current residency programs in psychiatry. In addition, the APA Committee on Medical Education has developed a brochure, "Choosing Psychiatry," directed toward medical students. Copies are available from the Office of Education.

The office has sponsored several symposia to assist members in the use of *DSM-III*. The first was a two-day conference developed in collaboration with Columbia University and held in New York City in December 1979. There were three other one-day symposia: one during February in Houston, one during March in San Francisco, and one during April in Boston. These symposia were clinical and practical in nature and well received by the 1,500 participants.

The important work of helping APA members, especially those who do not attend annual meetings, to meet their continuing education requirements is primarily carried out through the district branches and Area Councils and through other national organizations. APA and the Office of Education have served as educational consultants and helped to plan and review programs for Category I CME credit; this past year, APA sponsored 225 programs for a total of 1,976 hours of Category I CME credit. In addition, the office has fostered the development of self-study materials, including the "Survey of Psychiatry," a self-learning package consisting of audiotapes, background materials, syllabus, workbook, and assessment exercises.

The Office of Education also continues to work with the large number of components housed within the APA Council on Medical Education and Career Development, implementing the various policies and recommendations that emanate from the Council.

It should be noted that the office coordinates many aspects of psychiatric education in the United States and relates not only to other associations and to APA components but also to policy makers. Many of the major problems facing psychiatry during the 1980s will have a substantial educational component and I am pleased that we have become increasingly proactive in these matters.

GOVERNMENT RELATIONS

This division, under the capable guidance of Mr. Jay Cutler, provides the interface for APA policy with the legislative and executive branches of the federal government. At the same time it provides APA insight into, and analysis of, the health policy development process of Congress and the executive branch so that we can develop policy on these activities. This staff also provides support to the Joint Commission on Government Relations and to the Councils on Aging and on Governmental Policy and Law.

In an effort to respond to district branch concerns, the division is attempting to develop the capacity to identify major state legislative activities of common concern to all district branches and to provide the branches with analytic state

government relations information, serving as an informational resource on such major issues. For example, the division provided Vanderbilt University with updated information on the governance issues for community mental health centers; provided the San Diego District Branch with detailed information on the conflict between the HMO law and the HEW regulatory interpretation; and provided the Kentucky District Branch with background material on pending legislation dealing with reimbursement of other mental health professionals for the treatment of nervous, mental, or emotional disorders. The division also compiled a 50-state survey of laws dealing with patient rights provisions as a resource for this legislative issue at the local level.

Mr. Cutler's report deals in depth with APA Congressional testimony and APA legislative initiatives in the 96th Congress. He is to be congratulated on his continued attention to legislative issues of importance and concern to all of psychiatry.

OFFICE OF MINORITY AFFAIRS

A sizeable percentage of the work done in this department continues to focus on matters related to mental health and underrepresented groups, i.e., children, minorities, and women.

The APA/NIMH Fellowship Program, under Dr. Jeanne Spurlock's able direction, remains a positive force in recruiting and supporting minority residents in psychiatry. There were 59 applicants this year to the APA/NIMH Fellowship Program and 14 fellowships were awarded. The new Fellows include a native Hawaiian interested in child and community psychiatry, a Hispanic resident planning to work in community psychiatry, and an American Indian who expects to work in the area of cross-cultural psychiatry.

The staff directs a major percentage of its time and effort toward supporting the work of the Council on Children, Adolescents and Their Families and of the Council on National Affairs.

In addition to her many liaison activities with a variety of organizations, her membership on the Graduate Medical Education National Advisory Committee, and on the ABPN Committee on Certification in Child Psychiatry, Dr. Spurlock continues her teaching contributions to the child psychiatry training program at Children's Hospital, and to the medical student education program at Howard University and at the Uniformed Services Medical School.

PROFESSIONAL AFFAIRS

Dr. Henry H. Work, Deputy Medical Director and Director of Professional Affairs, provides staff assistance to the Assembly through the District Branch Office; to the Council on Research and Development; to the Scientific Program Committee (and chairs the Staff Committee on the Annual Meeting); to the Consultation and Evaluation Services Board; to the Achievement Awards Board; and to the Program Committee for the annual Institutes on Hospital & Community Psychiatry. Dr. Work also serves as member or officer of more than 9 other organizations (in particular as secretary of the Group for the Advancement of Psychiatry and secretary-general of the American College of Psychiatrists).

Professional correspondence is a very large part of the activities of this office. People from all over the country write to APA requesting help for themselves, relatives, and friends who suffer from mental illnesses. These letters demand personal attention, which is promptly offered. Our colleagues write to us for general and specific advice related to the mental health field. Young people have also learned that APA is a source of information on careers. So voluminous are these requests that Dr. Work and his staff prepared a pamphlet on how to become a psychiatrist. Requests for career information in 1979 totaled 1,433.

Some changes occurred in this office during 1979: staff support to the H&CP Service (including the Film Loan Library and Supplementary Mailings) is now provided by the *H&CP* journal staff.

Although recognizing that this is a time of fiscal stringency, Dr. Work has emphasized that there must not be any cutback on the quality of services rendered to our members and to the public, and the entire staff joins in these sentiments.

Dr. Work's report more fully discusses the 31st H&CP Institute, held in New Orleans in September 1979. However, I did want to mention that this was a very successful meeting, with over 800 persons registered. The theme, "Myths, Slogans and Bandwagons: A Realistic Appraisal," was well received and the evaluation comments stressed the high quality of the program.

PUBLIC AFFAIRS

In 1979 Mr. Robert L. Robinson retired as Director of Public Affairs. A search committee, chaired by Dr. Shervert Frazier, is currently reviewing resumes of applicants for this job. During this period Mr. Ron McMillen, Acting Director, has kept the division functioning. Media relations were dominant during 1979, following up on the Snowmass conference for national media writers held in September 1978. Efforts were made to present a more positive view of psychiatry in the public press, radio, and television. During 1979 *Time* and *Newsweek* both featured psychiatry in cover articles which emphasized newer directions in psychiatry. Following the telecast of "One Flew Over the Cuckoo's Nest," NBC aired a special segment of "Prime Time Sunday" that presented a positive view of ECT. Also, many newspapers featured positive articles on ECT. Mr. McMillen's report highlights media coverage in 1979.

Another major activity during 1979 was responsibility for the production of *DSM-III* and of a completely revised 5th edition of *A Psychiatric Glossary*. Promotional activity by this division accounted for advance sales of 30,000 copies of *DSM-III* and 6,000 of *A Psychiatric Glossary*. Staff also supervised the publication of three new Task Force reports.

New projects initiated during the year included a series of books for lay audiences on psychiatry, a new project that will allow reporters to prepare advance articles on the annual meeting, and planning for the 1980 national media conference for editors and publishers.

CONCLUSION

These are just a few highlights of Central Office staff activities. I urge each of you to take this report home and care-

Report of the Speaker

I AM PLEASED to report that the Assembly of District Branches is alive and well, that its officers are optimistic and enthusiastic about its accomplishments and its future, and that its members, your elected Representatives and Deputy Representatives, have worked hard and well on your behalf during the past year. This year the relations between the Board of Trustees and the Assembly have matured to a level of mutual respect. I have the sense of a team, working together to confront and solve some of the most complex and perplexing problems ever to face our profession, our organization, and our patients' lives. I feel indebted to our President, Alan Stone, who took great effort to consult with me and with the Assembly at every turn. Although Dr. Stone did not always agree with me or with the Assembly, his fairness and openness to diverse opinions and policies set a very high example for those who follow him. I should like to acknowledge as well the crucial roles the APA staff have played in the development of the Assembly-Board relations. At the helm is our trusted colleague and friend, Mel Sabshin, whose support of the Assembly and its officers is ever felt and rarely commended. Henry Work, who has been my friend, professor, and mentor for more than 20 years, has been unselfish with his time, advice, and occasionally his criticism. Ms. Ann Whinnie brings to her job 25 years of experience with APA and the Assembly and reminds us that our "new" ideas were already old when she started working here. The innovation has been Ms. Jeanne Robb in her role of Board-Assembly affairs coordinator. She has visited the Area Councils, developed agenda for meetings, and played a central role in the writing of a procedures handbook for the Assembly. APA members have every reason to be proud of the dedicated, professional personnel who work so hard and care so much about our organization and its objectives.

Einstein once remarked that he liked to state things as simply as possible, "but not simpler." This has been a very complex year; stating it simply would minimize the difficulty of the problems and the agonizing nature of some of the decision making. Nonetheless, I must be brief and can only highlight some of the year's significant issues and accomplishments. I will leave the report of good news to the President and the Medical Director and limit my report to seven major problem areas—Money, Education, Politics, Bureaucracy, Law, Internal Organization, and Future Planning. The Assembly and the District Branches have been most concerned with these problems during the past year.

MONEY

Reflecting the inflationary aspects of the national economy, the costs of operating the Association increased significantly during the past several years. Because of careful fiscal planning and budgeting, a dues increase was not necessary until this year. How unfortunate that it should come just at the culmination of more than five years of planning and debate over a new headquarters for our national office, and during the sharpest rise in inflation since World War II. The Assembly and Board carefully weighed the alternatives and decided to levy an assessment on each dues-paying member and ask for additional contributions from them and from the non-dues-paying members as well. They also decided to institute a modest registration fee at the Annual Meeting. The process through which these difficult decisions were made as well as the timeliness of the final actions are examples of our organization working at the highest level of cooperation and efficiency. This course of action has received support from large constituencies in the organization, and almost every District Branch president sent a letter to the members in support of these fiscal decisions.

National and state fiscal cutbacks were also of vital concern to the Assembly. The threatened termination of research and training funds could not have come at a worse time for our psychiatric residency education programs. During a period when we are facing a decline in the number of psychiatric residents, when psychiatry is a specialty of low interest to medical students, and when one-third to one-half of these medical students cannot distinguish between the roles of psychiatrists, psychologists, and social workers, we must place a high priority on strengthening our teaching centers, not in dismantling them. Some states, notably California, are facing severe cutbacks that threaten public education, particularly state hospital-community mental health programs. We must develop new alliances to challenge these issues, as well as look to new relationships with industry and private funding sources.

EDUCATION

The conflicting attitudes toward Continuing Medical Education also concern the Assembly. The compliance of members in reporting their required hours of CME activities, although very high, nonetheless reveals that many members are having trouble with this requirement. The cost to APA in monitoring is high, and the problem of dealing with noncompliant members is perplexing. The Assembly has been presented with an action paper calling for the discontinuation of the mandatory CME reporting now required by our Consitution and By-Laws. There is also confusion at the national level over the accreditation of CME activities After the AMA resigned from the Liaison Committee for CME and appointed a new Committee for Accreditation of CME, APA found itself with a foot in each committee. The Assembly played an important role in developing the original CME guidelines for APA. It will continue to keep a close watch on national developments and the district branches' proposals for future policies.

POLITICS

For several years the Assembly has urged the development of guidelines for psychiatrists in their professional rela-

This is an edited version of the report presented by the Speaker of the Assembly to the annual business meeting in San Francisco, Calif., May 5, 1980.

tionships with nonpsychiatrist mental health professionals. The need for guidelines became even more urgent with the lawsuits in Virginia and Ohio. The delay involved in adopting these guidelines reflects more on the difficulty of developing them than on the efficiency of our organization. The Assembly feels that some sort of guidelines are needed as soon as possible. With the passage of time, they can be modified and augmented as may be required.

The Equal Rights Amendment has also presented the Assembly with a dilemma. The support of the economic boycott has been one of the most divisive issues in the recent history of APA. The Assembly has supported ERA and has urged the Board on several occasions to back its support by not meeting in non-ERA states. Referenda on three occasions have indicated that the members do not support the Assembly in this strategy. Many members of the Assembly viewed the recent referendum as a less than ideal way to resolve this issue. Most Assembly members felt that presentation to a forum of elected representatives, providing a full discussion of all points of view, followed by a vote of the Board of Trustees, would have been far better than a last minute referendum presented to the members without prior notification and with little public discussion in *Psychiatric News*. In fact, in the fall the Assembly urged the Board not to submit a referendum on ERA this year. However, the Constitution and By-Laws permit individual members to submit referenda in this manner without review by the Assembly. Perhaps this points to a deficiency in our procedures that should be revised in the future. On an issue of this magnitude, hasty action is of little benefit to ourselves, our patients, or our organization.

On the national political level, the Assembly supported the creation of the American Psychiatric Political Action Committee. This important structure will make it possible for individual psychiatrists to become involved in influencing the creation and modification of legislation in ways which were not possible before. The Assembly will watch with great interest how this independent body functions and what implications it might have for similar developments on the district branch and Area levels.

BUREAUCRACY

With the promulgation of the new Consolidated Standards for Psychiatric Facilities by the Joint Commission on the Accreditation of Hospitals, it became clear that psychiatric facilities were facing an almost overwhelming task of understanding and meeting the thousands of criteria. Assembly members found several sections to be unacceptable to psychiatry, particularly the section dealing with the Medical Staff. In the new standards the Medical Staff gives way to the Clinical Staff. Other areas of treatment planning, patients' rights, medical audits, and review activities made dramatic changes in hospitals' conceptualization of patient care. Administrators were expected to spend thousands of hours of professional time attempting to meet the criteria. Often standards relating to similar activities were dispersed throughout the document, making compliance frustrating and difficult. The Assembly alerted the Board to the problems and the Board, through its Council on Mental Health Services and with the help of the Medical Director, moved quickly to take some remedial action. The Assembly cannot help but wonder whether a voluntary organization such as JCAH really represents a great advantage over the federal government. The Assembly will continue to play a role in watching and advising as the year progresses.

Filing forms for third-party payers is a tedious, taxing business for all of us. When confronted with the arbitrary and often discriminatory treatment insurance companies give our patients, it is small wonder that most of us feel angry and frustrated. Peer review is often seen as a screen for denial of insurance benefits to those who need them most and an insult to our integrity and sense of professional responsibility. It has been difficult for the Assembly to support the efforts of APA's CHAMPUS project and the work with the Aetna Insurance Company in developing a new program of psychiatric peer review tied to insurance benefits under these programs. Legitimate concerns about confidentiality notwithstanding, the Assembly has become convinced that without the peer review provisions contained in these programs, third-party coverage for all psychiatric treatment will be jeopardized. The Assembly has urged caution and careful review before expanding the program to include other carriers; efforts of the Assembly members of the ad hoc committee studying these projects have been of considerable help in changing some of the questionable practices that could have threatened confidentiality and at the same time have facilitated the research and evaluation efforts that may pave the way to greater coverage for our patients. The Assembly will continue to participate in these important studies and in the final decisions about the future of these activities.

LAW

There is a Mexican curse: "May there be a lawyer in your life." Since I assumed the office of Speaker there has been a lawyer in my life every day. Fortunately, Joel Klein has been on our side, advising us and helping us to understand and to act. Currently cases of great importance are being tried in courts all over the country. Right to refuse treatment and right to treatment cases sometimes confound those of us who believe that scientific, rational medical judgment is superior to jurisprudence in determining treatment issues. The most recent action of APA in the abortion case before the U.S. Supreme Court exemplifies the timely participation by our legal staff in issues important to our profession. We badly need a position statement on the civil commitment of adults. As is the case with the guidelines for working with nonpsychiatrist mental health professionals, the document need not be considered a final product. The Assembly hopes that a policy will be adopted soon for use in the courtrooms and with the legislatures.

INTERNAL ORGANIZATION

No report of the Speaker in recent years would be considered complete without an update on the progress made following the Key Conference. This year Assembly members participated in an Ad Hoc Committee on Reorganization, paying particular attention to the Council and component structures. As a result of their study, the committee recommended that the Reference Committee be restructured and the timing of the meetings altered to permit the new Joint Reference Committee to serve both the Board and the Assembly. Proposals for these changes will be presented during

this meeting, and the proposed changes in the Constitution and By-Laws will be on the ballot in 1981. The Assembly endorses these changes and believes that they will lead to greater efficiency and cost effectiveness.

FUTURE PLANNING

One of the keys to effective budgeting lies in prioritizing activities and eliminating those activities with the lowest priorities. In order to establish priorities, it is necessary to have long-range planning that determines which activities will be needed in the future and which activities may be phased out. Under the current system of line-item budgeting, it is not possible to differentiate such activities; hence, cost containment falls like a meat axe across the board. The Assembly listened to an eloquent description of long-range planning by Milton Greenblatt, chairperson of the Ad Hoc Committee, and endorsed his recommendations that APA join with a professional planning group to develop long-range plans for the Association. Participation by Assembly members in the process will allow for full discussion by most of the constituencies in APA and provide a more rational approach to cost containment and effective use of APA resources.

VALEDICTION

The year has not been simple, and the problems that have arisen have been taxing, yet I have grown and learned much as a result of my experience as Speaker. In retrospect I enjoyed it immensely. My sadness in leaving the office is alleviated by the confidence that I have in the new Speaker, Mel Lipsett, and by my conviction that his wisdom and experience will provide him with the skill needed to guide the Assembly and APA through these troubled times.

ROBERT O. PASNAU, M.D.

Report of the Speaker-Elect

SHAKESPEARE APTLY described the seven ages of man. We can loosely compare them with the development of the Assembly in its birth and growth over the past 27 or so years. We have come from infancy to adulthood. Here we part a little with the Bard and have to synthesize some of the stages. Combining the stages of soldier and statesman, we must fight to maintain our principles of effective treatment for our patients and must espouse and sustain our objectives with a variety of groups. We must help educate those groups, such as legislators, about the value of our objective of effective, professional treatment. We also need to exhibit the generativity and creativity Erikson defined along with our collective selves in the trichotomy of members as self, and Assembly as family existing in the third part of the trichotomy—a rapidly changing society.

With this meeting we enter a new decade, already filled with less than happy portents for the future in regard to psychiatric care and marked by a decline in interest in public mental health care. This is not a phenomenon that has suddenly erupted; it has been looming ever larger over the past decade. However, it is a phenomenon that we have been more effectively rising to meet, challenge, and battle. We are aware of the discussions about budgets at the national, state, and local levels. The philosophy is "guns before butter," which translates into a reduction of human services, including mental health care. Here in California we are faced with a referendum called Proposition 9, to be voted on in June. If it passes, it will further reduce income to the state. The State Director of Mental Health has suggested closing the few remaining state hospitals, returning the patients to their communities, but without appropriate funding for their care. It is not surprising that some patients are beginning to show up in the criminal justice system.

In preparation for this report, I did some research into the reports of past Speakers-Elect. My findings proved interesting, stimulating, encouraging, and at times disconcerting. One universal theme that prevailed was that of increasing membership participation. Currently this theme, which fits in well with our thrust toward greater democratization, is essential for our continued growth and development. I believe we need to aid the increased development of the Area Councils and the more active participation of the District Branch Councils and membership in the procedures and processes of our organization. One possibility which I raise for your consideration is that the district branch representative who is liaison to a task force or committee develop a mini-task force within his district branch to assist him. The participation of the Assembly has been invaluable in the development of *DSM-III* and Council reports. Our members in the district branches are a reservoir of much needed talent.

We are embarking on a new process in our organization—the process of functional budgeting. It is an exciting concept that will enable us to more sharply define objectives, goals, and priorities. We have grown in undertaking new activities vital to us in today's world. We have initiated many excellent programs, encompassing many activities. Unfortunately, there is a limited budget, restricted even more by inflationary pressures. There is also the specter of diminishing public and government support for human services. In our Association we have to establish our own process for what we consider to be our most important ways of achieving the objectives outlined in our Constitution. At the March 22 meeting of the Assembly Executive Committee Dr. Jack White told us that approximately 150 functions had been defined. Obviously some will have a higher priority than others, but how do we decide which these should be? It is my belief that the Assembly, via the Area Councils and the district branches, should have an important voice in the delineation and selection of the priorities.

This can only be done by an involved and informed membership. Three issues that I feel deserve a high priority are proactive involvement in legislation, research, and public information. We have developed a voice at the federal level; we now need to assist the development of a potent voice at the state level. Many district branches and some Area Councils have already done this. I feel it is essential that we assist those district branches and Area Councils which do not have such a system. We also need to push for more attention to research in psychiatry by encouraging closer liaison between the district branches and the departments of psychiatry within their jurisdictions. We need to let people know of our concerns about the care of the mentally ill and to enlist community support for good professional care.

It is my contention that we have to take a searching look at the process of referendum. The concept is an excellent one. However, I fear we are drifting toward governance by referenda. I do not feel that this is in the best interests of APA and recommend careful thiking about the process and its ramifications.

I am mindful of and pleased by the honor you have bestowed on me. The Speaker is the moderator in the Assembly and represents your voice at the Board of Trustees. I shall try to carry on the worthy tradition of my predecessors.

MELVIN M. LIPSETT, M.D.

This is an edited version of the report presented by the Speaker-Elect of the Assembly to the annual business meeting in San Francisco, Calif., May 5, 1980.

Report of the Membership Committee

THE MEMBERSHIP COMMITTEE met October 16, 17, 18, and 19 (1979) at APA headquarters in Washington, D.C. During this period it discussed Fellowship criteria and appraised its own operations and functions, met with Dr. Carolyn Robinowitz to discuss Continuing Medical Education requirements, met with the Assembly Membership Committee to consider policy and action matters common to both committees, and acted on Fellowship nominations and membership issues.

The Membership Committee, both alone and in conjunction with the Assembly Membership Committee, reviewed the report of the Board of Trustees' Ad Hoc Committee on Fellowship Criteria. The committee felt that its conduct of the Fellowship reviews basically agreed with the report's spirit and recommendations. Indeed, many of the suggestions are already being practiced and in a careful, thoughtful, and judicious fashion. The committee has acted on the assumption that it must take into account the total person and his or her breadth of experience and skills.

Fellowship is an honor and the committee endorsed the concept of Fellowship by invitation rather than by individual application; it enthusiastically supported the suggestion that district branches take full responsibility for presentation of the most complete information possible for their nominees. Specifically, the committee feels that 1) letters of recommendation could be written by nonpsychiatrists as well as psychiatrists, 2) letters of recommendation should address the specific criteria and requirements for Fellowship, 3) there could be more definitive feedback about deferrals, with emphasis on the district branches' responsibility, 4) district branches might counsel certain Fellowship aspirants not to apply, and 5) psychiatrists should be aware of the different criteria, the different areas, and the point system used in judging applicants, while remembering that the committee's deliberations and processes are flexible and geared toward an assessment of the total person.

A basic understanding of, and agreement on, national standards and criteria for Fellowship are more important than mechanisms (such as the point system) for assessing nominees. We must increase communication among district branches, the Central Office, and this committee in order to improve the quality of information submitted on behalf of the nominees. Both committees strongly support better education of, and collaboration with, the district branches concerning Fellowship matters. The committee recommended conducting a workshop for Fellowship/Membership Chairpersons, as well as offering workshops to Area Councils. Proposals included a one-day workshop for district branch representatives, possibly at APA headquarters, followed by a series of smaller regional workshops, plus a voluntary workshop at the Annual Meeting.

Clearly, there is legitimate concern over defining the vari-

ous characteristics that "create" a Fellow. What do we mean by "outstanding," "with distinction," "depth and scope of knowledge," or "breadth of skills and interests"? "Excellence" requires not only better calibration but better documentation as well. Most importantly, this committee cannot be adversarial in nature and function; rather, it must be supportive and respond to the needs of the members. We welcome a dialogue on these matters.

In a somewhat related matter, concern has been expressed over defining the term "professional suitability" as currently noted in the APA By-Laws. This term appears as a criterion for APA membership. The Membership Committee along with the Assembly Membership Committee, struggled with a definition and interpretation; we developed a statement that the Board of Trustees at its December meeting referred back to us for further study. The Board suggested that the code of medical ethics may help clarify this term.

The inescapable fact of a decline in membership also confronts us. The 5.3% growth rate that occurred between 1975 and 1976 dropped to a 3% growth rate between 1978 and the present. There has also been a greater increase in the non-dues-paying membership than in the dues-paying membership. In 1975 the non-dues-paying membership was 11.9% of the total; in 1979 it was 13.7% of the total. This means that new members must be recruited, perhaps largely through local community efforts, if we are to maintain and enhance a dynamic APA.

Requests for exemption from CME requirements based on disability, illness, limited practice, and early retirement are now being, and will continue to be, submitted to the Membership Committee. In the process of reviewing the exemption requests, the committee has developed several guidelines concerning exemption from CME requirements which it will recommend to the Board of Trustees. The committee will be flexible and considerate in its actions, and, as in other matters, will need the district branches' help to justify and support the exemption requests.

In view of the large number of members—approximately 8,000—who have not yet requested CME certification, the committee recommended that a letter be sent immediately by the Office of Education reminding these members of the requirements and informing the noncomplying members that their membership may be in jeopardy. The committee also recommended that a grace period of at least one year be allowed before any member who has not complied with CME requirements is dropped. In fact, even a two-year grace period—up to July 1981—may be considered.

The committee reviewed its position on the current eligibility requirement for Fellowship that extends the number of years needed as a General Member from five to eight. The referendum changing the requirement occurred during March and April, and notification was sent to the district branches on May 7.

The committee agreed that it could not review nominations that did not meet the eight-year requirement, and felt that this action was in accord with the wishes of the electorate and the Board of Trustees (who could have, but did not, specify a later implementation date). Subsequently, a number of district branches expressed considerable dismay and chagrin that the committee did not review the nominations for which a waiver of the eight-year requirement had been requested. Although the committee felt it had acted fairly and in good faith, the expectations of the district branches had to be respected. The Board of Trustees, with the active support of the chairman of the Membership Committee and the Membership Office staff, fashioned a suitable compromise plan whereby anyone who has been a General Member for six years or more is eligible to apply for Fellowship this summer.

A summary of membership actions during calendar year 1979 is presented in table 1. The status of APA membership in January 1980 compared with January 1979 is presented in table 2.

PHILIP M. MARGOLIS, M.D.

Report of the Committee of Tellers

THE COMMITTEE OF TELLERS met on March 20, 1980, at APA headquarters to certify the results of the 1980 election. Ballots had been mailed on February 4 to 23,682 eligible voting members. Ninety undeliverable ballots were deducted from that number; the final number of eligible voting members was 23,592; 10,800 ballots were returned and included in the final vote tally (which represents 45.8% of the eligible voting members).

The Tellers acted on questionable ballots that had been held for their decisions. The Tellers also verified that all candidates for the 1980 election had certified the accuracy of their submitted biographical information and that all candidates had submitted the required statements of compliance with election guidelines.

The Committee of Tellers certified that the following individuals were elected to office: Daniel X. Freedman, M.D., President-Elect (70.2% of votes cast); Robert J. Campbell III, M.D., Vice-President (51.9% of votes cast); George H. Pollock, M.D., Treasurer (52.8% of votes cast); Elissa P. Benedek, M.D., Trustee-at-Large (55.4% of votes cast); John J. McGrath, M.D., Area III Trustee (64.7% of votes cast); and Paul F. Slawson, M.D., Area VI Trustee (59.1% of votes cast).

In order to have a valid election on constitutional changes, 40% of the eligible voting members must cast votes. An abstention is considered to be a vote cast and counts toward determining whether 40% has been reached. Of that number, two-thirds must approve amendments to the Constitution; a majority must approve amendments to the By-Laws. The results of the voting were: Article III (creates Elections Committee)—41.7% of eligible voters cast votes, amendment passes, with 83.6% in favor; Chapter 9.2 (defines functions of Tellers and Elections Committee—41.1% of eligible voters cast votes, amendment passes, with 80.8% in favor; Chapter 9.8 (composition of Elections Committee)—41.4% of eligible voters cast votes, amendment passes with 81.5% in favor; and Chapter 9.9 (institutes recall mechanism for officers)—37.9% of eligible voters cast votes; vote on this amendment is invalid as it failed to achieve required 40% of voters casting votes.

Finally, the Committee of Tellers certified the vote count on the referendum concerned with holding APA meetings in states that have not ratified the Equal Rights Amendment: 5,679 members voted in favor of the referendum, which represented 54.6% of votes cast; 4,461 members voted against the referendum, or 42.9% of votes cast; and 268 members abstained, or 2.6% of votes cast. The total number of votes cast was 10,408, representing 44.1% of eligible voting members.

On April 11, 1980, the Committee of Tellers recommended that the Board of Trustees accept the above results of the 1980 election, and the Board accepted them.

EDWARD C. KIRBY, M.D.

This is an edited version of the report presented by the Committee of Tellers to the annual business meeting in San Francisco, Calif., May 5, 1980.

Report of the Committee on Constitution and By-Laws

THE COMMITTEE ON CONSTITUTION AND BY-LAWS (CCBL) has appreciated the cooperation of the components and members of the Association who have shared issues with us or made recommendations to us that have helped us to carry out our functions this year. As chairperson, I wish to thank the members of the committee for their good work and thoughtful contributions, and APA's counsel, Joel Klein, and staff members, Lee Gurel and Carol Lehmann, for their patience, good sense, and helpfulness.

The APA membership recently approved amendments recommended by the CCBL and others to create an Elections Committee that would establish and oversee election policies. We hope this move will increase efficiency in elections, and lead to more orderly campaigning. The CCBL also recommended, and the Board accepted, changes in the *Operations Manual* that would shift some functions from the Tellers Committee to the Elections Committee.

At the Board's request, the CCBL proposed some brief, clear wording to the Board to be used if the Board chose to have another ERA referendum. (Since another ERA referendum subsequently came to the Board and the APA membership by petition, the Board chose not to add one of their own, no matter how clear.)

In a measure to improve what many APA members consider a troublesome lack of clarity in the wording of recent referenda, the CCBL proposed and the Board accepted a new mechanism for the *Operations Manual* that will review the wording of referenda for clarity.

The CCBL recommended to the Board retention of the words "professional suitability" in the By-Laws, Chapter 2, along with three clarifying paragraphs.

The CCBL obtained an opinion from Joel Klein on votes being taken by the Assembly at the annual business meeting. It is Mr. Klein's opinion that votes can be taken on any matter fairly raised by an Assembly member who questions an item in one of the reports presented, asks for a vote, and has his request seconded by another Assembly member. (Since this is the only meeting of the Assembly also regularly attended by APA members, who customarily sit with their representatives, this interpretation may provide greater attention and responsiveness to these reports.)

Still under review by the CCBL are matters regarding ethical issues, a possible limit to the size of the Assembly, a By-Law stating that resignations will not routinely be accepted if dues or ethical complaints are awaiting resolution, the status of By-Laws 4.2 and 6.3 vis-à-vis current APA appointment procedure, and an invitation to the Assembly to propose some words for the By-Laws defining Assembly powers and responsibilities.

The CCBL, in keeping with the requirements of the Constitution and By-Laws, is presenting to the membership the following proposed amendments, which have been approved by the Board of Trustees (see appendix 1). The proposed amendments are summarized as follows:

1. Chapter 1, Section 6: The change will bring the Constitution and By-Laws of the APA in line with ABPN requirements for residency training established in 1977.
2. Chapter 1, Section 7: The additional phrase in this section makes it consistent with requirements for other member categories and is in keeping with the policy of the Association.
3. Chapter 2, Section 1: The addition to this section clarifies that certification of membership applications is done by the Membership Committee.
4. Chapter 6, Section 7: The amendment changes the composition of the Reference Committee, adds two members of the Board and two of the Assembly—an interesting new point of influence for the Assembly—and removes voting power from the Council chairpersons. This was recommended by the Board's Ad Hoc Committee on Council Structure and has been approved by the Board.
5. Chapter 7, Section 1: We have proposed that current Chapter 7.1 be deleted and a new Chapter 7.1 be enacted both to bring the By-Laws in line with current Assembly procedure and to allow the Assembly some flexibility in choosing among several plans, currently being considered by the Assembly's Committee on Procedures, designed to improve Assembly representativeness.
6. Chapter 8, Section 6: The change clarifies exemptions from paying both dues and assessments.

After six years on the CCBL, I have reached the constitutional time for retirement. I am thankful to the former members of the committee with whom I served and to the current members—Drs. Scott Nelson, Elissa Benedek, Hugh Smith, Kathleen Mogul, and Arthur Zitrin—for their good work and willingness to devote their time to the business of the committee.

LAWRENCE HARTMANN, M.D.

This is an edited version of the report presented by the Committee on Constitution and By-Laws to the annual business meeting in San Francisco, Calif., May 5, 1980.

APPENDIX 1
Proposed Amendments to the APA Constitution and By-Laws

The proposals that follow were received within the 60-day deadline before the annual meeting and were presented at the annual business session. They will appear on the ballot in March 1981.

Note: The following changes in type style indicate the kind of change proposed in the Constitution and By-Laws: 1) italic=proposed additions to the Constitution and By-Laws (e.g., *"by resolution of the Assembly"*), and 2) brackets=proposed deletions from the Constitution and By-Laws (e.g., "may originate [either] . . ."). Articles and sections of the Constitution and chapters and sections of the By-Laws that are not listed here have not been subject to any proposed changes.

THE BY-LAWS

CHAPTER ONE. MEMBERS

6. General Members shall be physicians who have [had at least three years of] *completed* acceptable training and who have either a valid license to practice medicine or hold an academic, research, or governmental position that does not require licensure.

7. Fellows shall have been General Members for at least eight years and shall have made a significant contribution to the field of psychiatry. *Fellows must have either a valid license to practice medicine or hold an academic, research, or governmental position that does not require licensure.* At its discretion the Board, upon recommendation of the Membership Committee, may waive the requirement for eight years as a General Member. The criteria and procedures for selection and nomination of General Members for Fellowship shall be established by the Board and the Membership Committee and shall apply uniformly for all District Branches.

CHAPTER TWO. MEMBERSHIP PROCESSING

1. Admission to membership shall require valid election by the appropriate District Branch approved to process membership applications, with certification *by the Membership Committee of the Association* that constitutional requirements for membership have been met.

CHAPTER SIX. COUNCILS, COMMITTEES, BOARDS, AND OTHER ORGANIZATIONAL ENTITIES

7. A Reference Committee shall be established to act upon the concerns of the several councils *and commissions* and to refer matters [to and from the Board.] *from the councils and commissions to the Board and/or the Assembly and from the Board or the Assembly to them.* It shall be composed of the President-Elect, who shall be the chairperson; [the chairperson of each council] the Speaker-Elect of the Assembly, *who shall be vice chairperson; two members of the Board of Trustees; two members of the Assembly;* and the Medical Director. *Ex-officio non-voting members shall be the chairpersons of the councils and commissions.*

CHAPTER SEVEN. THE ASSEMBLY AND THE DISTRICT BRANCHES

[1. The Assembly shall be comprised of an elected representative and alternate representative from each District Branch.]

1. There shall be an Assembly of District Branches whose voting members shall be elected and shall include at least a) one representative from each District Branch, and b) an Executive Committee including Area Representatives and Assembly Officers.

CHAPTER EIGHT. PRIVILEGES AND RESPONSIBILITIES

6. Every Fellow, General Member, Associate Member, and Member-in-Training shall pay both dues and assessments as determined by the Board and the District Branches. All other categories of membership shall be exempt from paying dues *and assessments* to both the Association and its District Branches. A dues-paying member shall be exempt from paying such dues *and assessments* when the sum of that member's years of active membership in the Association plus the member's age at the start of the fiscal year shall equal 95.

1979 Annual Report of the American Board of Psychiatry and Neurology, Inc.

OFFICE AND MEMBERS OF THE BOARD

At its Policy Meeting on November 15, 1979, the Board elected the following officers: Dr. Marc H. Hollender, President, Dr. Melvin D. Yahr, Vice President, Dr. Dewey K. Ziegler, Secretary, Dr. Richard M. Steinhilber, Treasurer, and Dr. James N. Sussex, Executive Committee Member at Large.

Dr. John A. Talbott was elected to succeed Dr. Donald G. Langsley, who completed his term of four years in December 1979. Drs. Patrick F. Bray and S. Mouchly Small were elected to serve second terms of four years.

The 1979 Directors of the American Board of Psychiatry and Neurology, Inc., are as follows:

Nominated by the American Medical Association: Dr. Robert J. Joynt* (term expires December 1980), Dr. Richard M. Steinhilber* (term expires December 1981), Dr. T.R. Johns II* (term expires December 1982), Dr. James N. Sussex* (term expires December 1982), and Dr. S. Mouchly Small* (term expires December 1983).

Nominated by the American Neurological Association: Dr. Leonard Berg (term expires December 1981), Dr. Melvin D. Yahr* (term expires December 1982), Dr. Patrick F. Bray* (term expires December 1983), and Dr. John R. Calverley (term expires December 1980).

Nominated by the American Psychiatric Association: Dr. Marc H. Hollender* (term expires December 1981), Dr. Carolyn B. Robinowitz (term expires December 1982), Dr. Alfred M. Freedman* (term expires December 1982), Dr. Richard I. Shader (term expires December 1980), Dr. John A. Talbott (term expires December 1983).

Nominated by the American Academy of Neurology: Dr. Audrey S. Penn* (term expires December 1982) and Dr. Dewey K. Ziegler* (term expires December 1982).

EXAMINATIONS

Part I

At the Part I (written) examination on April 16, 1979, 1,672 psychiatrists were examined; 1,337 (80%) passed, 335 (20%) failed. A total of 423 neurologists were examined; 337 (80%) passed, 86 (20%) failed.

For the 1980 Part I examination, 1,797 psychiatrists and 530 neurologists have accepted assignment. (See table 1 for the number of candidates declared eligible and notified for Part I in 1980 and table 2 for a comparison of these figures for other years.)

TABLE 1
Number Declared Eligible and Notified for Part I Written Examination April 22, 1980

Item	Psychiatry	Neurology	Total
Number declared eligible and notified	1,952	546	2,498
Number who declined or withdrew	155	16	171
Number remaining for written examination as of March 1980	1,797	530	2,327

TABLE 2
Comparison of Number Declared Eligible and Notified for Part I Examination

Item	1974	1975	1976	1977	1978	1979
Total eligible	2,098	3,146	3,113	2,419	2,581	2,521
Total who accepted examination	1,821	2,408	2,391	2,087	2,361	2,367
Total who actually appeared	1,627	2,240	2,191	1,860	2,159	2,095

Part II

There were 437 candidates—352 psychiatrists and 85 neurologists—present at the Part II examination given in San Francisco, Calif., January 8–9, 1979 (see table 3). A total of 744 candidates—579 psychiatrists and 165 neurologists—were examined in New Orleans, La., April 9–10, 1979 (see table 4). There were 516 candidates—396 psychiatrists and 120 neurologists—present at the Part II examination given in Denver, Colo., June 9–10, 1979 (see table 5). The Fall 1979 Part II examination was administered to 1,027 candidates in Chicago, Ill., October 29–30, 1979 (see table 6). Of these candidates, 818 were psychiatrists and 209 were neurologists.

Future examination sites for 1980 are Los Angeles, Calif. (April 14–16), Milwaukee, Wis., (June 30–July 1), and New York, N.Y. (October 27–28).

CHILD PSYCHIATRY

Members of the current Committee on Certification in Child Psychiatry are Dr. Jeanne Spurlock, chairperson; Dr. Joseph Green, vice-chairperson, Dr. Irving Philips, secretary, Dr. Norman Bernstein, Dr. Norbert Enzer, Dr. Elva Poznanski, and Dr. Michael Cohen, liaison from the American Board of Pediatrics.

At its February 26–27, 1979, examination in Pittsburgh, Pa., the committee examined a total of 172 candidates. The number of passing candidates was 121 or 70%. Of the remaining 51 candidates, 74 (8%) conditioned the examination, while 37 (22%) failed.

At its September 27–29, 1979, meeting the committee agreed to move the deadline for filing applications for the

This is an edited version of the report of the American Board of Psychiatry and Neurology, Inc., to the American Psychiatric Association in Washington, D.C., April 11, 1980.

*These Directors are serving their second term of four years and are not eligible for reappointment.

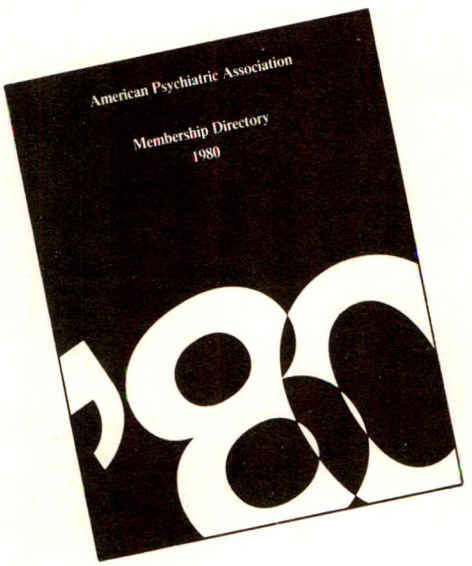
examination in child psychiatry to October 1. Those candidates successfully completing the adult psychiatry Boards in the fall would be eligible to make application after this deadline.

The committee is currently engaged in development of an operations manual.

BOARD DECISION AND ITEMS OF INTEREST

1. The ABPN hosted a meeting of the Trans-National Certification group in Chicago on May 18–19, 1979. This group consists of representatives from Canada, the United Kingdom; Australia, and New Zealand and has been set up to study equivalent patterns of training and examinations. This was the first Trans-National Conference of its type and the reaction was extremely favorable. Future conferences are being planned and the ABPN intends to continue its representation in this group.



2. At its January 1979, Part II examination in San Francisco, the American Board of Psychiatry and Neurology developed a supplemental training session for new psychiatry examiners. This was highly successful and is being repeated at each examination.

At its policy meeting on November 15–17, 1979, the American Board of Psychiatry and Neurology took the following significant actions: 1) affirmed its requirement of an unlimited license to practice medicine in the U.S. or Canada in or-

der to be admitted to examination and expressed its concern regarding the altered requirement of the state of New Hampshire in issuing licenses limited to a particular specialty; 2) moved the deadline for receipt of applications for the Part I examination to September 1, effective for the 1981 examination; 3) agreed to submit recertification plans for psychiatry and for neurology to the ABMS; 4) agreed to continue to work with the AADPRT, AADCP, and APA to develop means whereby program heads and department chairpersons participate more actively in the certification process; and 5) agreed to adopt the following guidelines for ABPN examiners involved in Board review courses: The American Board of Psychiatry and Neurology, Inc., wishes to call to the attention of the profession that it is questionable ethics for a physician conducting, or participating in, any educational enterprise, particularly continuing education, to notify in any fashion those taking such courses that he/she is or has been a Director of, or examiner on, the ABPN. Such notification may be taken to mean that the material presented by that physician is in some way authorized or sponsored by the ABPN or that the course content and/or examination is in some way identical with that used in ABPN examinations.

Order Your Copy of the 1980 Membership Directory Now!

The latest listing of APA members (as of January 31, 1980) has just been published. Unlike previous editions, the 1980 Membership Directory, largely at the urging of President Dr. Donald G. Langsley, contains telephone numbers as well as names, addresses, membership class and membership status. A new format provides easy access to the alphabetical and geographical listings.

Another new addition to this Directory is a section containing the names and addresses of District Branch Executive Secretaries. Also included in this Directory is a list of Officers, the Board of Trustees and the Assembly, as well as past APA meetings, past Officers, Honorary and Distinguished Fellows and a membership table. This publication will provide readers with information about the APA and the most comprehensive listing of the membership since the 1977 Biographical Directory.

April 1980. Approximately 300 pages. Order #151. $13.00.

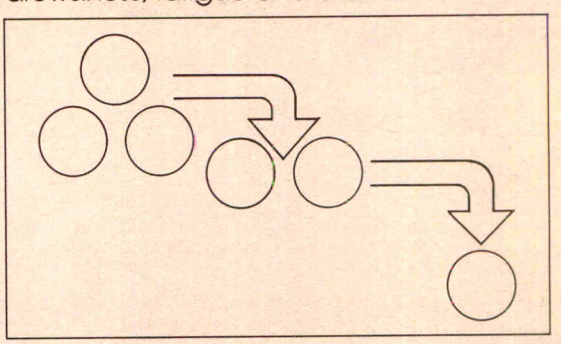
Fast-in

24-hour blood level curve of 10-mg oral dose of diazepam in a single healthy subject.



Smooth-out

Smooth: Avoids sudden symptom breakthrough Because of its fast and complete absorption, peak blood levels of Valium (diazepam/Roche) are achieved in 60 to 90 minutes after a single dose for a rapid initial calming effect. Typically, with an appropriate dosage regimen (e.g., 5 mg *t.i.d.*) Valium builds in a uniform and predictable way to a steady-state level within 5-7 days, without accumulating beyond. With Valium the excretion rate is similarly consistent and predictable. When pharmacologic support is no longer needed, the overlapping half-lives of diazepam and its metabolites insure a gradual elimination process. Because metabolites of short-acting benzodiazepines are inactive, blood levels of these drugs decrease more rapidly without benefit of a tapering effect.

Consistent therapeutic effect even when an occasional dose is omitted Once steady-state is achieved, sudden symptom breakthrough is highly unlikely, even if a dose is forgotten or skipped. That's because the half-life of Valium—27-37 hours—provides the advantage of self-tapering action, complementing your gradual reduction of the patient's dosage and smoothing his transition to independent coping.

To discontinue smoothly... Gradual discontinuation of medication—while rarely necessary after short-term therapy—*is* good medical practice in patients who have received high doses for extended periods. When dosage is tapered, untoward side effects can be avoided. Throughout therapy, in fact, side effects are infrequent with Valium and are seldom more serious than drowsiness, fatigue and ataxia.

Before prescribing, please see summary of product information on following page. ROCHE®

2-mg, 5-mg, 10-mg scored tablets

Valium®

Smooth transition to independent coping

diazepam/Roche ℞

Valium®
diazepam/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Management of anxiety disorders, or short-term relief of symptoms of anxiety; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam/Roche) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10;*Prescription Paks of 50, available in trays of 10.

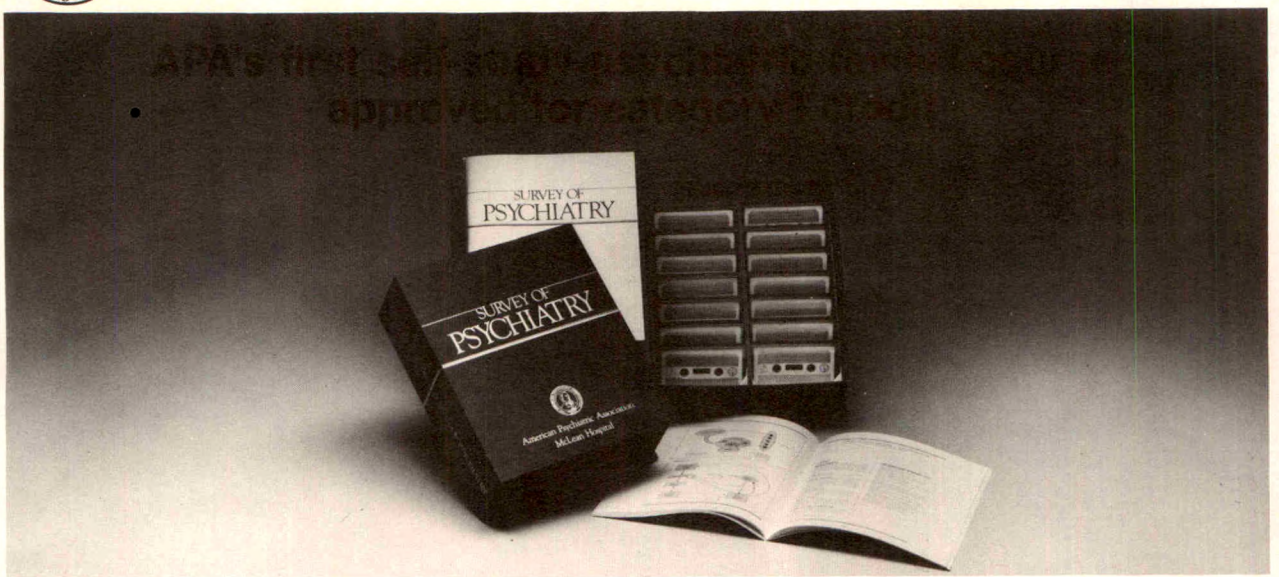
Help cure cancer write now.

Thanks to your help, the tide is beginning to turn. The past few years have brought new discoveries in chemotherapy.

And new diagnostic techniques that combine the "eyes" of X-ray machines with the "brains" of computers. And successful new programs of combination therapies.

And there are promising reports coming in from research laboratories all over the world.

We now have everything we need to save about half the people who get cancer.



Please don't quit on us now.

We're halfway there.

American Cancer Society

We want to cure cancer in your lifetime.

SURVEY OF PSYCHIATRY

This *new* 16-hour program offers a fresh, comprehensive overview of psychiatric theory, practice, and research. Authored by a distinguished faculty, specialists in their field, SURVEY OF PSYCHIATRY presents *completely new,* up-to-date information for the practicing physician who wants to keep abreast of the current state of the art, and may assist for certifying exams (such as the American Board of Psychiatry and Neurology).

Course Director:
Shervert H. Frazier, MD.
Psychiatrist-in-Chief
McLean Hospital Professor of Psychiatry
Harvard Medical School

SURVEY OF PSYCHIATRY has been designed to meet the needs of the busy physician.

- Versatile programs — ideal for home study, teaching, seminars, group study, and refresher courses
- Maximum educational and review benefits in easy-to-use format
- Convenient, flexible — no time spent away from practice

Course Components:

- Audiocassettes — 14 live lectures on 14 audiocassettes
- Course Syllabus (94 pages) — fully illustrated with tables, charts and slide reproductions, plus a concise bibliography for further study
- Test Section — questions and computerized test sheet with self-addressed mailing envelope for registrants desiring Continuing Medical Education Category I credits

Credit Statement:
As an organization accredited by the Liaison Committee on Continuing Medical Education (LCCME) to provide continuing medical education, the American Psychiatric Association certifies that this continuing medical education offering meets the criteria for up to 16 hours of LCCME Category I CME credit, provided it is used and completed as designed.

breaking
through

In marked agitation with depression symptomatic relief may make the patient more accessible and responsive.

Rapid relief of marked agitation in many patients
The tranquilizer component alleviates symptoms of agitation and anxiety within a few days, without apparent dulling of mental acuity. Hypnotic effects from the tranquilizer component appear to be minimal, particularly in patients permitted to remain active. However, TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks.

Highly effective antidepressant action
The antidepressant component relieves symptoms of depression such as poor concentration and feelings of hopelessness as well as early morning awakening; adequate relief of symptoms may take a few weeks or even longer.

Helps break barriers to psychotherapy
As symptoms are relieved, many patients often communicate more effectively, become more cooperative, and are able to return to normal daily activities.

More prescribing convenience
There are now *five* tablet strengths of TRIAVIL for ease of dosage adjustment. For many patients with agitation and depression, you can now initiate therapy with one TRIAVIL® 4-50, containing 4 mg perphenazine and 50 mg amitriptyline HCl, b.i.d. The regimen is simple, economical, and may well enhance patient compliance.

Treatment with TRIAVIL—a balanced view:
TRIAVIL is contraindicated in CNS depression from drugs, in the presence of evidence of bone marrow depression, and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to overdosage of other drugs or mask other disorders. The possibility of suicide in depressed patients remains until significant remission occurs. Such patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

For marked agitation with depression

dual-action®

Triavil

containing perphenazine and amitriptyline HCl

MSD
MERCK SHARP & DOHME

Copyright © 1979 by Merck & Co., Inc.

Please see following page for a brief summary of prescribing information.

More dosage strengths than any other formulation containing a tranquilizer and an antidepressant

dual-action TRIAVIL®

containing perphenazine and amitriptyline HCl

Available:
TRIAVIL® 2-25: Each tablet contains
2 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 2-10: Each tablet contains
2 mg perphenazine and 10 mg amitriptyline HCl.
TRIAVIL® 4-50: Each tablet contains
4 mg perphenazine and 50 mg amitriptyline HCl.
TRIAVIL® 4-25: Each tablet contains
4 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 4-10: Each tablet contains
4 mg perphenazine and 10 mg amitriptyline HCl.

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); evidence of bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with TRIAVIL. Therapy should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given concomitantly with guanethidine or similarly acting compounds since TRIAVIL may block the antihypertensive action of such compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. Dosage of anticonvulsive agents may have to be increased. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time, particularly in high doses. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of some untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides. There is sufficient experimental evidence to conclude that chronic administration of antipsychotic drugs which increase prolactin secretion has the potential to induce mammary neoplasms in rodents under the appropriate conditions. There are recognized differences in the physiological role of prolactin between rodents and humans. Since there are, at present, no adequate epidemiological studies, the relevance to human mammary cancer risk from prolonged exposure to perphenazine and other antipsychotic drugs is not known.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close supervision and careful adjustment of dosages are required. Paralytic ileus may occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Amitriptyline HCl may enhance the response to alcohol and the effects of barbiturates and other CNS depressants.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.
Perphenazine: Extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) have been reported and can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw. Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. Fine vermicular movements of the tongue may be an early sign of the syndrome. The full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; other adverse reactions reported with various phenothiazine compounds, but not with perphenazine, include grand mal convulsions, cerebral edema, polyphagia, pigmentary retinopathy, photophobia, skin pigmentation, and failure of ejaculation.

The phenothiazine compounds have produced blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); and liver damage (jaundice, biliary stasis).

Pigmentation of the cornea and lens has been reported to occur after long-term administration of some phenothiazines. Although it has not been reported in patients receiving TRIAVIL, the possibility that it might occur should be considered.

Hypnotic effects, lassitude, muscle weakness, and mild insomnia have also been reported.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs and must be considered when amitriptyline is administered. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; increased intraocular pressure; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness, weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

An Equal Opportunity Employer

PSYCHIATRISTS

Child psychiatrists, interested and preferably experienced with developmentally-disabled persons, invited to apply for staff positions at major teaching, university affiliated hospital. Duties include direct patient services, consulting and teaching staff in other disciplines.

For information write:
Ms. Barbara Stein,
Wrentham Project Manager,
Children's Hospital Medical Center.

We offer competitive starting salaries commensurate with experience, an outstanding fringe benefits package and the opportunity for professional growth and advancement.

CHILDREN'S HOSPITAL
MEDICAL CENTER BOSTON

300 Longwood Avenue
Boston, MA 02115

An Affirmative Action
Equal Opportunity Employer

STAFF PSYCHIATRISTS

Harlem Valley Psychiatric Center is an innovative, fully accredited, nationally recognized psychiatric facility serving 450 inpatients on its campus in Wingdale, N.Y. (foothills of the Berkshires, within 2 driving hours of New York City) with a complex network of innovative outpatient programs serving 3,000 in Putnam and Westchester Counties.

Minimum qualifications: N.Y.S. license and completion of approved residency. Salary range $40,020 to $43,560; if board certified, $43,560 to $48,707 (full time basis). Both full and part time positions for inpatient units at the Wingdale campus for acute admissions program, chronic geriatric program. Excellent Civil Service fringe benefit package. Medical school affiliation and on-grounds housing available.

Forward CV to Paul R. Dropauer, Personnel Dept.
HARLEM VALLEY PSYCHIATRIC CENTER

An equal opportunity/Affirmative action employer

DIRECTOR

Dept. of Psychiatry

567-bed teaching hospital and a major affiliate of State University Downstate Medical Center is seeking a board certified Psychiatrist with extensive teaching, clinical and administrative experience to direct its psychiatric program.

The Director will work in a half-time staff capacity and will have qualifications that would warrant a faculty appointment at the Downstate Medical Center.

Please direct your CV and correspondence to:

An Equal Oppty Employer M/F

Lithobid

Slow-Release Lithium Carbonate 300 mg.

Before prescribing, see complete prescribing information in Rowell literature. The following is a brief summary.

WARNING
Lithium toxicity is closely related to serum lithium levels, and can occur at doses close to therapeutic levels. Facilities for prompt and accurate serum lithium determinations should be available before initiating therapy.

Indications: Treatment of manic episodes of manic-depressive illness. Maintenance therapy prevents or diminishes the intensity of subsequent episodes in manic-depressive patients with a history of mania.

Warnings: Lithium should generally not be given to patients with significant renal or cardiovascular disease, severe debilitation or dehydration, sodium depletion, or to patients receiving diuretics.

Lithium therapy has been reported in some cases to be associated with morphologic changes in the kidneys.

Caution patient and family to watch for diarrhea, vomiting, tremor, mild ataxia, drowsiness, or muscular weakness as signs of lithium toxicity, and to discontinue therapy and contact a physician should they occur. Patients receiving combined therapy with lithium and an antipsychotic should be monitored closely for early evidence of neurologic toxicity and treatment discontinued promptly if such signs appear. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery).

Lithium should not be used in pregnancy, especially during the first trimester, unless potential benefits outweigh possible hazards.

Not recommended for children under 12.

Precautions: Lithium tolerance is greater during the acute manic phase and decreases when manic symptoms subside.

Lithium therapy may lead to sodium depletion. Normal diet (including salt) and adequate fluid intake (2500-3000 ml) must be maintained, at least during initial stabilization period. Protracted sweating or diarrhea can decrease tolerance; in such cases, administer supplemental fluid and salt.

Each tablet contains 40 mg of sodium chloride, equivalent to 15.7 mg of sodium.

Sweating, diarrhea, and concomitant infection with elevated temperatures may require temporary reduction or cessation of dosage.

Adverse Reactions: Mild to moderate toxic reactions may occur at serum lithium levels from 1.5 to 2.5 mEq/L, and moderate to severe reactions at levels from 2.0 to 2.5 mEq/L. Fine hand tremor, polyuria, and mild thirst may occur during initial therapy and persist. Transient and mild nausea and general discomfort also appear during initial therapy. These effects usually subside with continued treatment or temporary reduction or cessation of dosage. If persistent, discontinue dosage.

Diarrhea, vomiting, drowsiness, muscular weakness, and lack of coordination may be early signs of toxicity and may occur at levels below 2.0 mEq/L. At higher levels, ataxia, giddiness, tinnitus, blurred vision, and a large output of dilute urine may be seen. Serum levels above 3.0 mEq/L may produce a complex clinical picture, involving multiple organs and systems. Serum levels should not exceed 2.0 mEq/L during acute phase.

The following reactions appear to be related to serum lithium levels, including levels within the therapeutic range: Neuromuscular—tremor, muscle hyperirritability (fasciculations, twitching, clonic movements of whole limbs), ataxia, choreo-athetotic movements, hyperactive deep tendon reflex; Central Nervous System—blackout spells, epileptiform seizures, slurred speech, dizziness, vertigo, incontinence of urine or feces, somnolence, psychomotor retardation, restlessness, confusion, stupor, coma; Cardiovascular—cardiac arrhythmia, hypotension, peripheral circulatory collapse; Gastrointestinal—anorexia, nausea, vomiting, diarrhea; Genitourinary—albuminuria, oliguria, polyuria, glycosuria; Dermatologic—drying and thinning of hair, alopecia, anesthesia of skin, chronic folliculitis, exacerbation of psoriasis, xerosis cutis; Autonomic—blurred vision, dry mouth; Thyroid Abnormalities—euthyroid goiter and/or hypothyroidism (including myxedema) with lower T_3 and T_4. I^{131} uptake may be elevated; EEG Changes—diffuse slowing, widening of the frequency spectrum, potentiation and disorganization of background rhythm; EKG Changes—reversible flattening, isoelectricity or inversion of T-waves; Miscellaneous—fatigue, lethargy, transient scotomata, dehydration, weight loss, tendency to sleep.

Reactions unrelated to dosage include: transient EEG and EKG changes, leukocytosis, headache, diffuse nontoxic goiter with or without hypothyroidism, transient hyperglycemia, generalized pruritus with or without rash, cutaneous ulcers, albuminuria, worsening of organic brain syndromes, excessive weight gain, edematous swelling of ankles or wrists, thirst or polyuria, sometimes resembling diabetes insipidus, and metallic taste. A single case of a syndrome resembling Raynaud's has been reported.

Dosage and Administration: *Acute Mania*—900 mg b.i.d. or 600 mg t.i.d. (1800 mg per day) usually will provide serum lithium levels ranging between 1.0 and 1.5 mEq/L. Serum levels should be determined twice per week until serum level and clinical condition have been stabilized.

Long-Term Control—900 mg to 1200 mg per day in two or three divided doses usually will maintain serum lithium levels at 0.6 to 1.2 mEq/L. Serum lithium levels should be monitored at least every two months.

How Supplied: 300 mg peach-colored tablets, imprinted "ROWELL 7514" in red, are supplied in bottles of 100 and 1000.

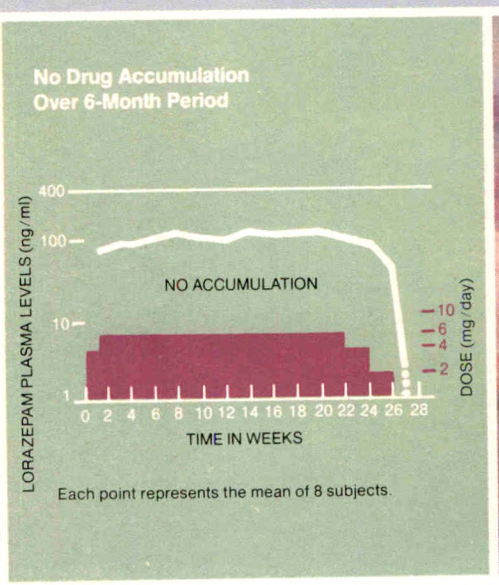
ROWELL LABORATORIES, INC.
BAUDETTE, MINN. 56623

Do lithium dosage schedules keep your patients going around in circles?

Slow-Release Lithobid enables twice-a-day dosing as a practical route to better patient compliance. Patients on conventional lithium dosage forms can be converted to new Lithobid at the same daily dose, divided b.i.d. All patients on long-term lithium maintenance therapy will appreciate the convenience of this reduced dosage frequency.

Conventional tablets or capsules cause serum lithium spikes. New Lithobid blunts these peaks and keeps post-absorption serum levels within bounds.

Lithobid™
Slow-Release Lithium Carbonate 300 mg.



Now you can convert your lithium patients to this convenient, new b.i.d. dosage.

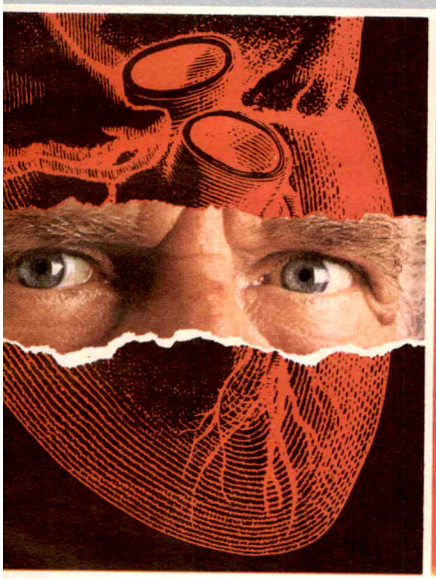
How do you choose a minor tranquilizer?

Wyeth Laboratories
Philadelphia, PA 19101
TM

Pharmacokinetics

Ativan (lorazepam) is eliminated more rapidly than other benzodiazepines; generates no clinically active metabolites. The half-life of free lorazepam is about 12 hours; steady-state blood levels are attained in 2-3 days. (Comparable data for diazepam: 20-50 hours and at least 7-10 days.) Ativan shows no evidence of accumulation, even when given in high doses for as long as 6 months. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)



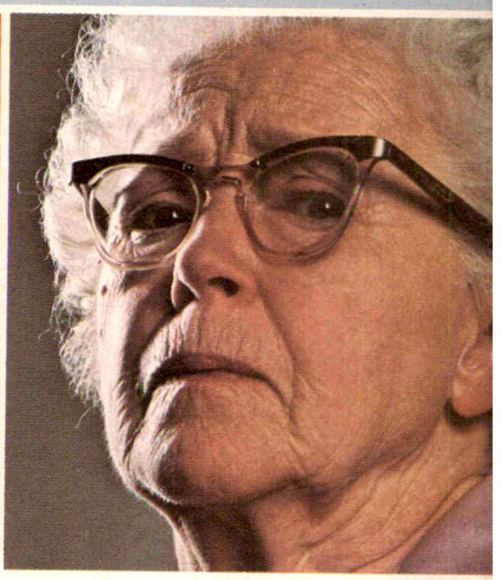
Anxiety neuroses

In many nationwide studies involving thousands of patients with anxiety neuroses Ativan (lorazepam) consistently provided significant relief of anxiety, tension, agitation and irritability as measured by standard Hamilton, Global (physician rated) and 35-Item (patient self-rated) scales.

Copyright © 1979, Wyeth Laboratories Div. of AHPC, N.Y., N.Y. All rights reserved.

They're all about the same, aren't they? Until recently, that seemed to sum up the prevalent attitude about the benzodiazepines. After all, they all work similarly and all are effective anxiolytics. With seven of these compounds now available, however, differences have begun to emerge. Foremost among them: different metabolic pathways, which distinguish the relatively short-acting Ativan (lorazepam) from long-acting diazepam, clorazepate and chlordiazepoxide. At the same time, your choice can be made with confidence in the clinical record of Ativan, which confirms its value in anxiety neuroses and in significant anxiety associated with functional or organic disorders, as well as in older patients.

Consider the record of Ativan:



Anxiety in cardiovascular disorders

Ativan (lorazepam) has been specifically evaluated and found effective in seven common protocol, double-blind studies involving 423 patients (211 on Ativan) those anxiety was related to organic and functional cardiovascular disorders. The cardiovascular component as not, of course, been shown to be significantly benefited by such therapy.

Anxiety in gastrointestinal disorders

So far, nine common protocol, double-blind studies of Ativan have focused on anxious patients with functional or organic gastrointestinal complaints (457 patients, 234 on Ativan). Ativan was clearly effective in reducing the anxiety of these patients. The gastrointestinal component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in the aging patient

Because its simple metabolism is not readily impaired with advancing age, and accumulation is not likely to present a problem, Ativan is a good choice for older patients. Those who have trouble swallowing solid medication appreciate the small Ativan tablet, which is tasteless and disintegrates within seconds in water or fruit juice.

Ativan® (lorazepam) for Anxiety

See important information on following page.

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

Introducing...

Navane®
(thiothixene HCl)
Intramuscular
For Injection
5 mg/ml

new potency for rapid control of acute psychiatric emergencies

Now, Navane Intramuscular 5 mg per ml provides a more concentrated dosage form for rapid control of severely disturbed behavior associated with acute psychosis. Navane Intramuscular, in carefully monitored doses, "...can produce significant improvement within hours and increase the accessibility of these [acutely disturbed] patients to more gradual methods of pharmacological treatment as well as to socio-environmental intervention and psychotherapy."[1]

Rapid tranquilization usually can be achieved without excessive sedation.[1] Clinically significant hypotension, often seen with other injectable antipsychotic agents, is rare with Navane Intramuscular therapy.[1-3] If extrapyramidal symptoms occur, they are usually readily controlled by dosage adjustment or antiparkinson agents.

ROERIG Pfizer
A division of Pfizer Pharmaceuticals
New York, New York 10017

For a brief summary of Navane prescribing information, including adverse reactions and contraindications, please see the following page of this advertisement.

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml, 5 mg/ml

BRIEF SUMMARY OF PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml, 5 mg/ml

Contraindications. Navane (thiothixene) is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy*– Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration of Navane to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children– The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration– As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane (thiothixene). Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudo-parkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia: antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leukocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution; Navane For Injection– Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane (thiothixene) Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate– In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

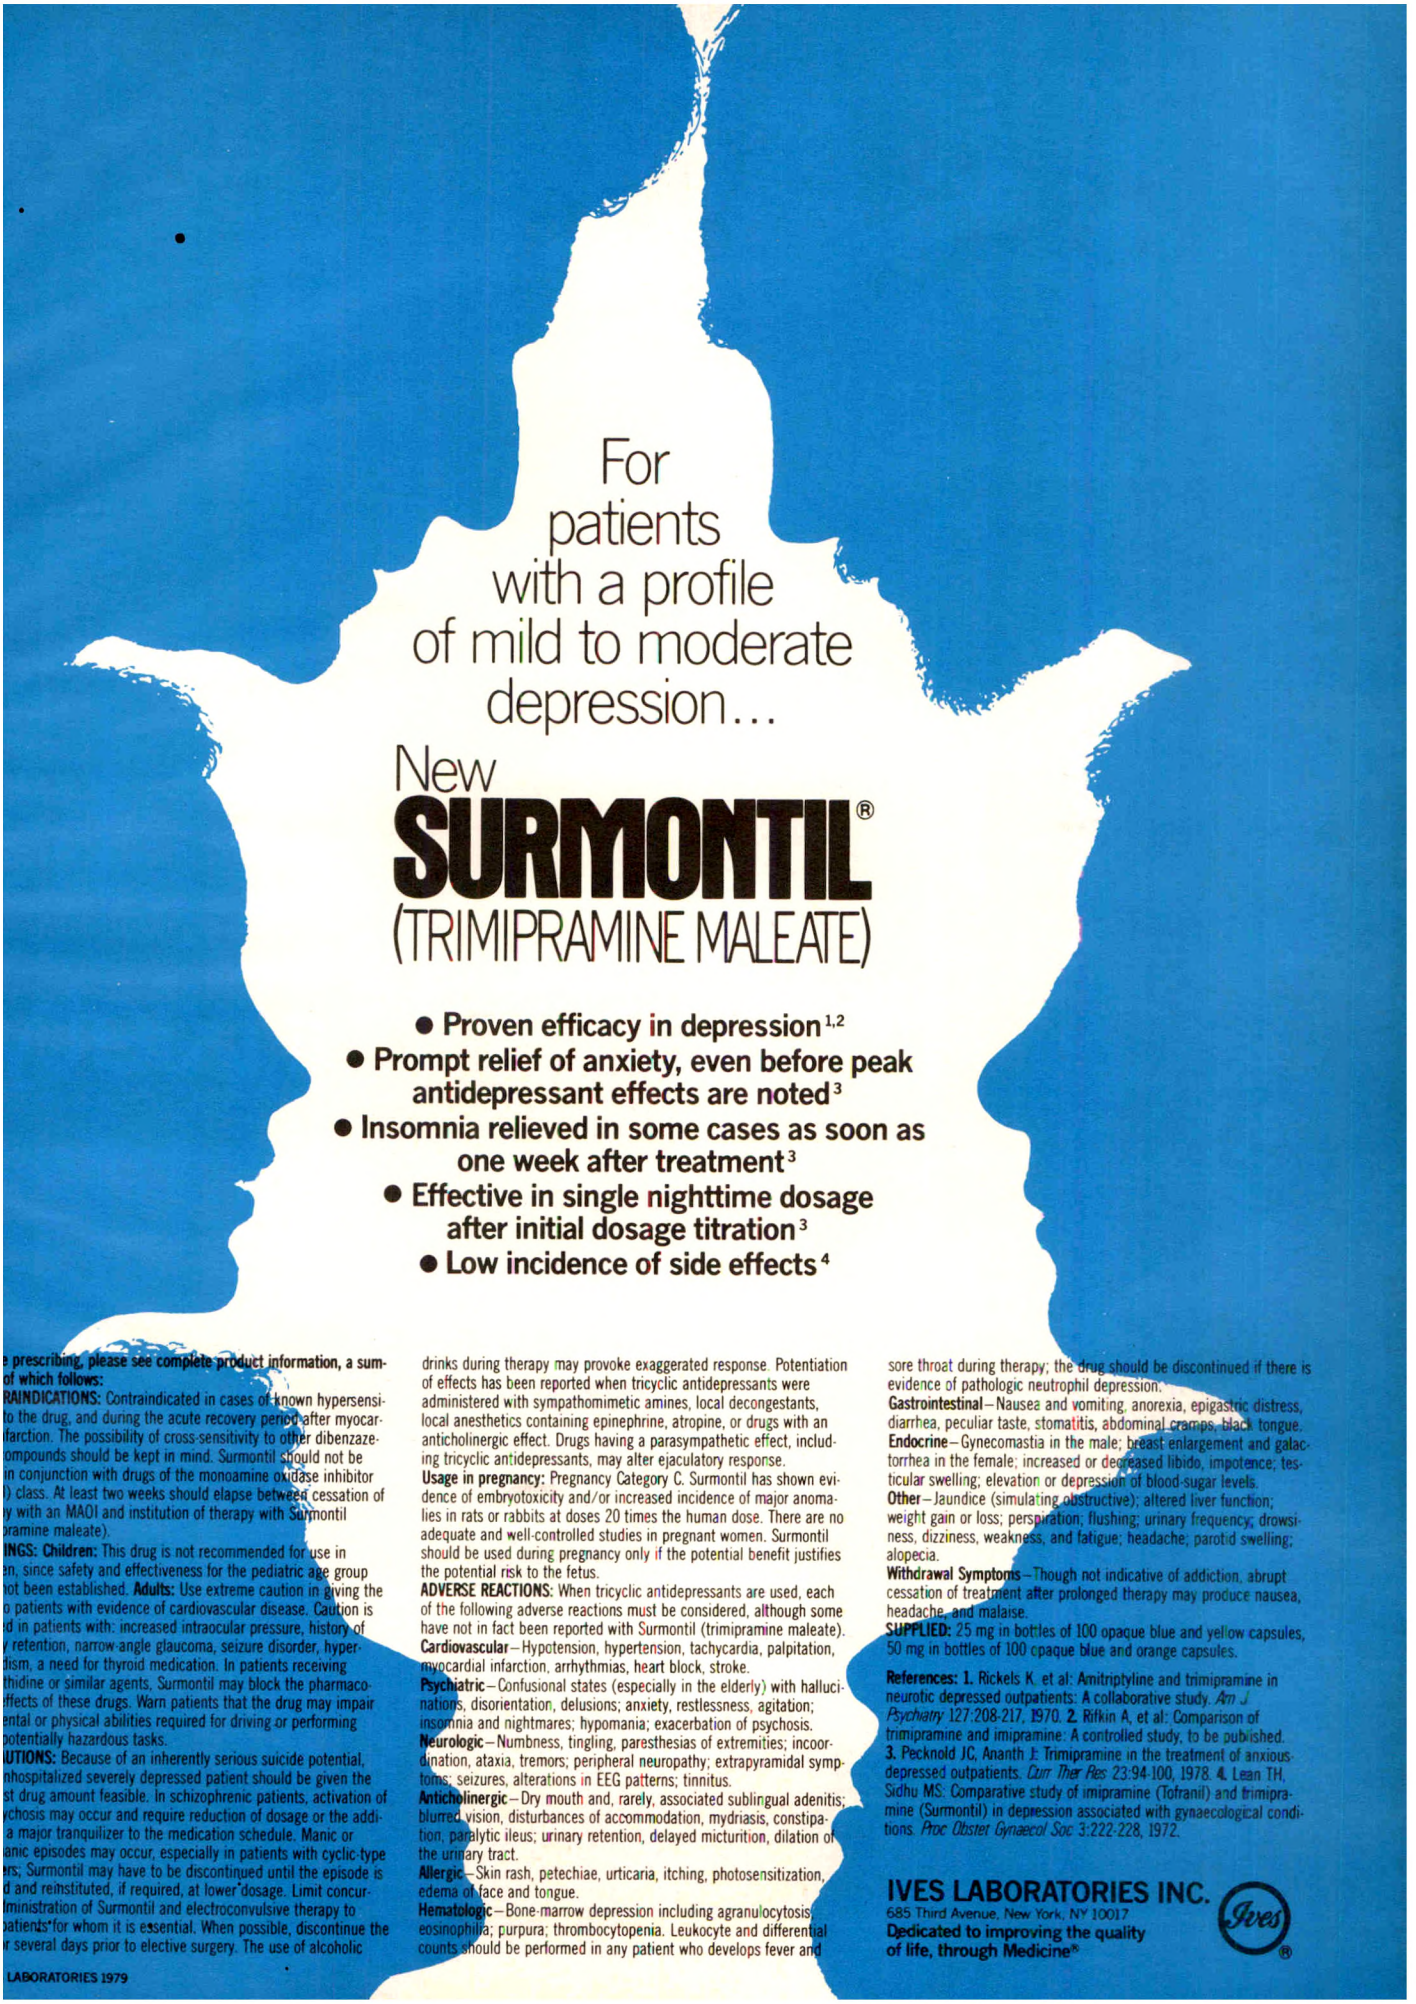
If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Stimulants that may cause convulsions (e.g. picrotoxin or pentylenetetrazol) should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg of thiothixene in bottles of 100, 1,000, and unit-dose pack of 100 (10 x 10's). Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100, 500, and unit-dose pack of 100 (10 x 10's).

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg, and in 30 ml (1 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, and 5 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).



Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10 vials. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

Navane (thiothixene hydrochloride) Intramuscular For Injection is available in amber glass vials in packages of 10 vials. When reconstituted with 2.2 ml of Sterile Water for Injection, each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene, and 59.6 mg of mannitol. The reconstituted solution of Navane Intramuscular For Injection may be stored for 48 hours at room temperature before discarding.

ROERIG Pfizer
A division of Pfizer Pharmaceuticals
New York, New York 10017

e prescribing, please see complete product information, a sum- of which follows:

RAINDICATIONS: Contraindicated in cases of known hypersensi- to the drug, and during the acute recovery period after myocar- farction. The possibility of cross-sensitivity to other dibenzaze- ompounds should be kept in mind. Surmontil should not be in conjunction with drugs of the monoamine oxidase inhibitor I) class. At least two weeks should elapse between cessation of y with an MAOI and institution of therapy with Surmontil ramine maleate).

INGS: Children: This drug is not recommended for use in n, since safety and effectiveness for the pediatric age group ot been established. **Adults:** Use extreme caution in giving the o patients with evidence of cardiovascular disease. Caution is d in patients with: increased intraocular pressure, history of retention, narrow-angle glaucoma, seizure disorder, hyper- dism, a need for thyroid medication. In patients receiving thidine or similar agents, Surmontil may block the pharmaco- ffects of these drugs. Warn patients that the drug may impair ental or physical abilities required for driving or performing otentially hazardous tasks.

UTIONS: Because of an inherently serious suicide potential, nhospitalized severely depressed patient should be given the st drug amount feasible. In schizophrenic patients, activation of ychosis may occur and require reduction of dosage or the addi- a major tranquilizer to the medication schedule. Manic or anic episodes may occur, especially in patients with cyclic-type rs; Surmontil may have to be discontinued until the episode is d and reinstituted, if required, at lower dosage. Limit concur- dministration of Surmontil and electroconvulsive therapy to patients for whom it is essential. When possible, discontinue the r several days prior to elective surgery. The use of alcoholic drinks during therapy may provoke exaggerated response. Potentiation of effects has been reported when tricyclic antidepressants were administered with sympathomimetic amines, local decongestants, local anesthetics containing epinephrine, atropine, or drugs with an anticholinergic effect. Drugs having a parasympathetic effect, includ- ing tricyclic antidepressants, may alter ejaculatory response.

Usage in pregnancy: Pregnancy Category C. Surmontil has shown evi- dence of embryotoxicity and/or increased incidence of major anoma- lies in rats or rabbits at doses 20 times the human dose. There are no adequate and well-controlled studies in pregnant women. Surmontil should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: When tricyclic antidepressants are used, each of the following adverse reactions must be considered, although some have not in fact been reported with Surmontil (trimipramine maleate).

Cardiovascular—Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric—Confusional states (especially in the elderly) with halluci- nations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurologic—Numbness, tingling, paresthesias of extremities; incoor- dination, ataxia, tremors; peripheral neuropathy; extrapyramidal symp- toms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic—Dry mouth and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis, constipa- tion, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic—Skin rash, petechiae, urticaria, itching, photosensitization, edema of face and tongue.

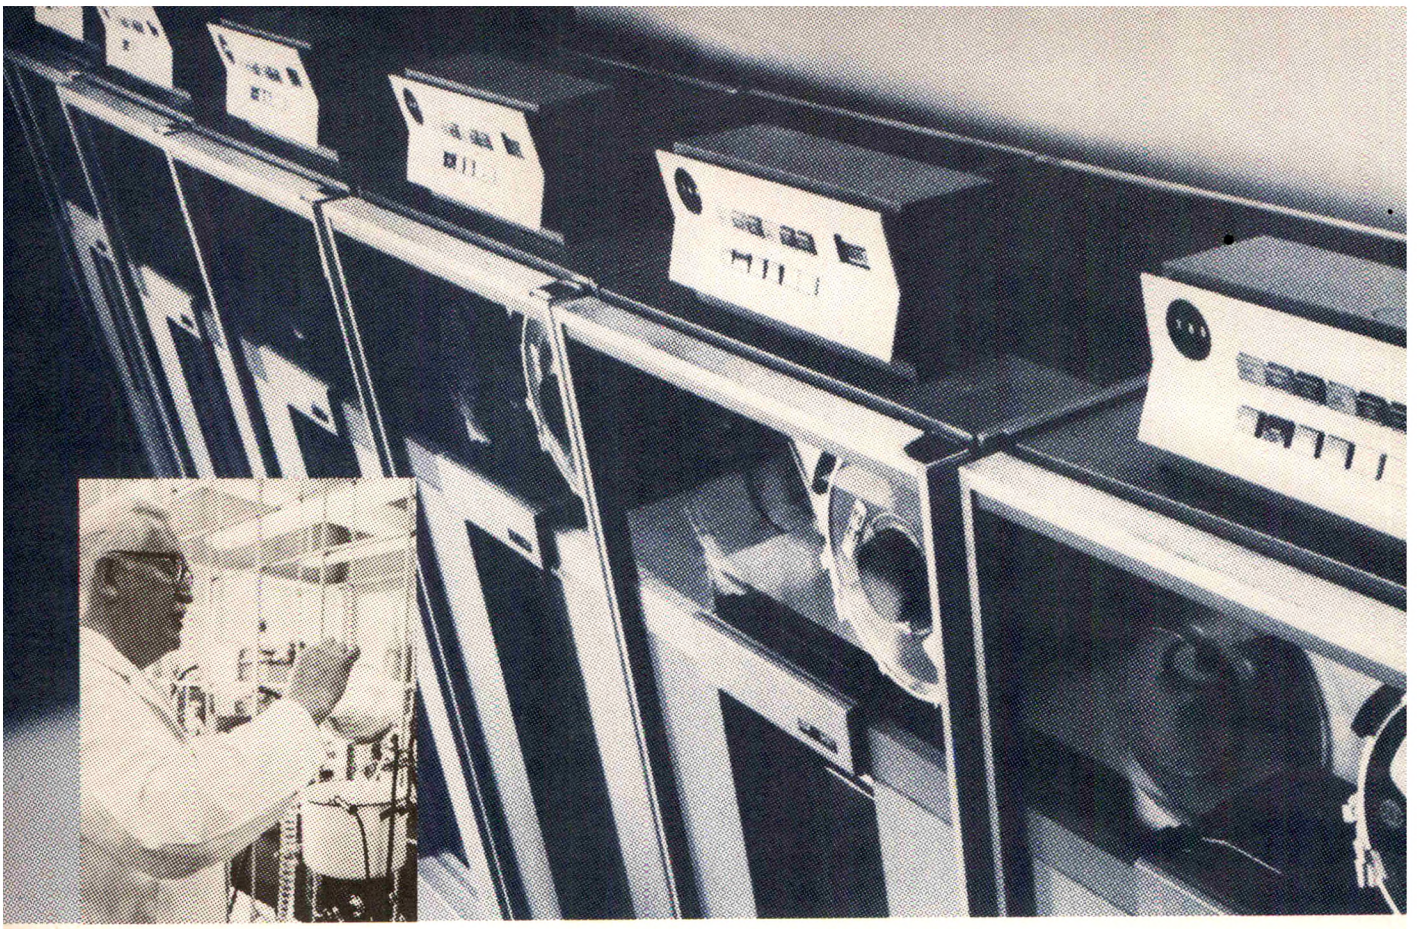
Hematologic—Bone-marrow depression including agranulocytosis; eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathologic neutrophil depression.

Gastrointestinal—Nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine—Gynecomastia in the male; breast enlargement and galac- torrhea in the female; increased or decreased libido, impotence; tes- ticular swelling; elevation or depression of blood-sugar levels.

Other—Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsi- ness, dizziness, weakness, and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms—Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.



SUPPLIED: 25 mg in bottles of 100 opaque blue and yellow capsules, 50 mg in bottles of 100 opaque blue and orange capsules.

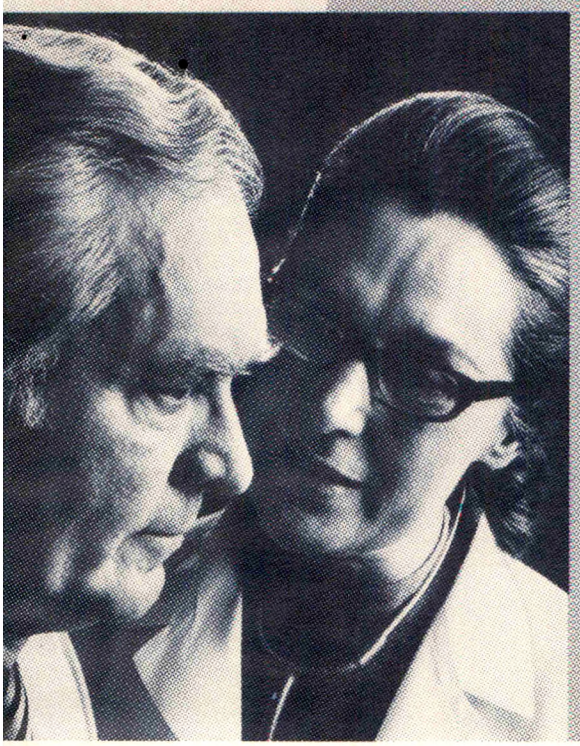
IVES LABORATORIES INC.
685 Third Avenue, New York, NY 10017
Dedicated to improving the quality of life, through Medicine®

Ives®



LABORATORIES 1979

proven antianxiety

Highly specific calming action virtually free of unwanted side effects: this was the remarkable clinical promise of Librium (chlordiazepoxide HCl). And today this promise continues to be fulfilled in a wide variety of patients you see every day.

ROCHE

The published record on Librium is enormous. So large, in fact, it had to be put into a computer data bank and retrieval system. It's a record that shows Librium is highly effective in relieving anxiety; that Librium is seldom associated with serious side effects; that Librium rarely interferes with mental acuity at proper doses; that Librium is used concomitantly with primary medications. However, as with all CNS agents, patients should be warned against hazardous activities requiring complete alertness, and about possible combined effects with alcohol.

performance

Librium® CV

chlordiazepoxide HCl/Roche

5mg, 10mg, 25mg capsules

synonymous with relief of anxiety

- ☐ An unsurpassed safety record
- ☐ Minimal effect on mental acuity, in proper dosage
- ☐ Predictable patient response
- ☐ Is used concomitantly with primary medications, such as anticholinergics and cardiovascular drugs

Please see next page for summary of product information.

Librium® 5mg, 10mg, 25mg capsules
chlordiazepoxide HCl/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states. Efficacy beyond four months not established by systematic clinical studies. Periodic reassessment of therapy recommended.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Warn patients that mental and/or physical abilities required for tasks such as driving or operating machinery may be impaired, as may be mental alertness in children, and that concomitant use with alcohol or CNS depressants may have an additive effect. Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Usual Daily Dosage: Individualize for maximum beneficial effects. *Oral–Adults:* Mild and moderate anxiety and tension, 5 or 10 mg *t.i.d.* or *q.i.d.*; severe states, 20 or 25 mg *t.i.d.* or *q.i.d.* *Geriatric patients:* 5 mg *b.i.d.* to *q.i.d.* (See Precautions.)

Supplied: Librium® (chlordiazepoxide HCl) *Capsules*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10. Libritabs® (chlordiazepoxide) *Tablets*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500. With respect to clinical activity, capsules and tablets are indistinguishable.

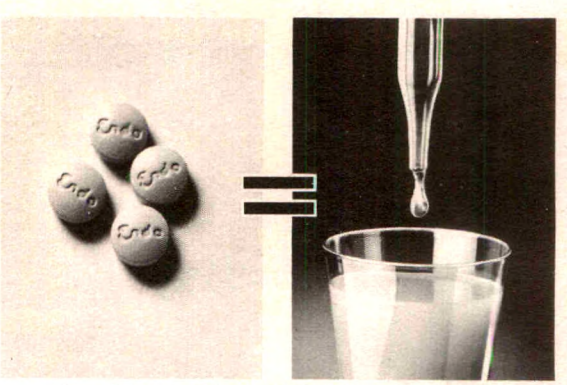
New
MOBAN®
molindone HCl
Concentrate
20 mg/ml
Easily administered
in fruit juice...has
a subtle cherry flavor
when taken alone



An effective antipsychotic agent with a favorable benefit/risk profile

NO incidence	excessive weight gain hepatotoxic changes ophthalmological changes persistent tardive dyskinesia skin pigmentation thyroid function changes tolerance development
LOW incidence	adverse drug interactions hematological changes hypotension nonpersistent symptoms of tardive dyskinesia sedation
MODERATE incidence	extrapyramidal reactions

This table compiled from clinical and field reports, according to the best available information.

For the schizophrenic patient

New MOBAN® molindone HCl Concentrate 20 mg/ml

four 25 mg tablets = 5 milliliters (100 mg)

Concentrated for maximum convenience of higher dosages...easy titration... enhanced compliance

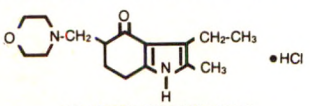
Initial dosage with MOBAN®

- usual starting dose is 50-75 mg/day
- may be increased to 100 mg/day in three to four days
- may be adjusted up or down according to response
- some patients with severe symptomatology may require an increase to 225 mg/day
- elderly and debilitated patients should be started on lower dosage

Please see next page for prescribing information.

Endo Laboratories DUPONT

An effective antipsychotic agent



MOBAN® molindone HCl

New dosage form... Concentrate 20 mg/ml

continuing...Tablets 5 mg, 10 mg, 25 mg

DESCRIPTION MOBAN (molindone hydrochloride) is a dihydroindolone compound which is not structurally related to the phenothiazines, the butyrophenones or the thioxanthenes.

MOBAN is 3-ethyl-6, 7-dihydro-2-methyl-5-(morpholinomethyl) indol-4 (5H)-one hydrochloride. It is a white crystalline powder, freely soluble in water and alcohol and has a molecular weight of 312.67.

MOLINDONE HYDROCHLORIDE

ACTIONS MOBAN (molindone hydrochloride) has a pharmacological profile in laboratory animals which predominantly resembles that of major tranquilizers causing reduction of spontaneous locomotion and aggressiveness, suppression of a conditioned response and antagonism of the bizarre stereotyped behavior and hyperactivity induced by amphetamines. In addition, MOBAN antagonizes the depression caused by the tranquilizing agent tetrabenazine.

In human clinical studies tranquilization is achieved in the absence of muscle relaxing or incoordinating effects. Based on EEG studies, MOBAN exerts its effect on the ascending reticular activating system.

Human metabolic studies show MOBAN (molindone hydrochloride) to be rapidly absorbed and metabolized when given orally. Unmetabolized drug reached a peak blood level at 1.5 hours. Pharmacological effect from a single oral dose persists for 24-36 hours. There are 36 recognized metabolites with less than 2-3% unmetabolized MOBAN being excreted in urine and feces.

INDICATIONS MOBAN (molindone hydrochloride) is indicated in the management of the manifestations of schizophrenia.

CONTRAINDICATIONS MOBAN (molindone hydrochloride) is contraindicated in severe central nervous system depression (alcohol, barbiturates, narcotics, etc.) or comatose states, and in patients with known hypersensitivity to the drug.

WARNINGS Usage in Pregnancy: Studies in pregnant patients have not been carried out. Reproduction studies have been performed in the following animals:

Pregnant Rats oral dose— 20 mg/kg/day—10 days
no adverse effect
40 mg/kg/day—10 days
no adverse effect

Pregnant Mice oral dose— 20 mg/kg/day—10 days
slight increase resorptions
40 mg/kg/day—10 days
slight increase resorptions

Pregnant Rabbits oral dose— 5 mg/kg/day—12 days
no adverse effect
10 mg/kg/day—12 days
no adverse effect
20 mg/kg/day—12 days
no adverse effect

Animal reproductive studies have not demonstrated a teratogenic potential. The anticipated benefits must be weighed against the unknown risks to the fetus if used in pregnant patients.

Nursing Mothers: Data are not available on the content of MOBAN (molindone hydrochloride) in the milk of nursing mothers.

Usage in Children: Use of MOBAN (molindone hydrochloride) in children below the age of twelve years is not recommended because safe and effective conditions for its usage have not been established.

MOBAN has not been shown effective in the management of behavioral complications in patients with mental retardation.

PRECAUTIONS Some patients receiving MOBAN (molindone hydrochloride) may note drowsiness initially and they should be advised against activities requiring mental alertness until their response to the drug has been established.

Increased activity has been noted in patients receiving MOBAN. Caution should be exercised where increased activity may be harmful.

MOBAN does not lower the seizure threshold in experimental animals to the degree noted with more sedating antipsychotic drugs. However, in humans convulsive seizures have been reported in a few instances.

EDO 854M580

The physician should be aware that this tablet preparation contains calcium sulfate as an excipient and that calcium ions may interfere with the absorption of preparations containing phenytoin sodium and tetracyclines.

MOBAN (molindone hydrochloride) has an antiemetic effect in animals. A similar effect may occur in humans and may obscure signs of intestinal obstruction or brain tumor.

ADVERSE REACTIONS—CNS EFFECTS The most frequently occurring effect is initial drowsiness that generally subsides with continued usage of the drug or lowering of the dose.

Noted less frequently were depression, hyperactivity and euphoria.

Neurological—Extrapyramidal Reactions Extrapyramidal reactions noted below may occur in susceptible individuals and are usually reversible with appropriate management.

Akathisia Motor restlessness may occur early.

Parkinson Syndrome Akinesia, characterized by rigidity, immobility and reduction of voluntary movements and tremor, have been observed. Occurrence is less frequent than akathisia.

Dystonic Syndrome Prolonged abnormal contractions of muscle groups occur infrequently. These symptoms may be managed by the addition of a synthetic antiparkinson agent (other than L-dopa), small doses of sedative drugs, and/or reduction in dosage.

Autonomic Nervous System Occasionally blurring of vision, tachycardia, nausea, dry mouth and salivation have been reported. Urinary retention and constipation may occur particularly if anticholinergic drugs are used to treat extrapyramidal symptoms.

Hematological There have been rare reports of leucopenia and leucocytosis. If such reactions occur, treatment with MOBAN may continue if clinical symptoms are absent. Alterations of blood glucose, liver function tests, B.U.N., and red blood cells have not been considered clinically significant.

Metabolic and Endocrine Effects Alteration of thyroid function has not been significant. Amenorrhea has been reported infrequently. Resumption of menses in previously amenorrheic women has been reported. Initially heavy menses may occur. Galactorrhea and gynecomastia have been reported infrequently. Increase in libido has been noted in some patients. Impotence has not been reported. Although both weight gain and weight loss have been in the direction of normal or ideal weight, excessive weight gain has not occurred with MOBAN.

Cardiovascular Rare, transient, non-specific T wave changes have been reported on E.K.G. Association with a clinical syndrome has not been established. Rarely has significant hypotension been reported.

Ophthalmological Lens opacities and pigmentary retinopathy have not been reported where patients have received MOBAN (molindone hydrochloride). In some patients, phenothiazine induced lenticular opacities have resolved following discontinuation of the phenothiazine while continuing therapy with MOBAN.

Skin Early, non-specific skin rash, probably of allergic origin, has occasionally been reported. Skin pigmentation has not been seen with MOBAN usage alone.

MOBAN (molindone hydrochloride) has certain pharmacological similarities to other antipsychotic agents. Because adverse reactions are often extensions of the pharmacological activity of a drug, all of the known pharmacological effects associated with other antipsychotic drugs should be kept in mind when MOBAN is used. Upon abrupt withdrawal after prolonged high dosage an abstinence syndrome has not been noted.

Tardive Dyskinesia Although rarely reported with MOBAN (molindone hydrochloride) symptoms were reversible upon discontinuation of therapy.

Tardive dyskinesia associated with other agents has appeared in some patients on long-term therapy and has also appeared after drug therapy has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). There may be involuntary movements of extremities.

There is no known effective treatment of tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear. Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked. It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time the syndrome may not develop.

DOSAGE AND ADMINISTRATION Initial and maintenance doses of MOBAN (molindone hydrochloride) should be individualized.

Initial Dosage Schedule The usual starting dosage is 50-75 mg/day.
- —Increase to 100 mg/day in 3 or 4 days.
- —Based on severity of symptomatology, dosage may be titrated up or down depending on individual patient response.
- —An increase to 225 mg/day may be required in patients with severe symptomatology.

Elderly and debilitated patients should be started on lower dosage.

Maintenance Dosage Schedule
1. Mild—5 mg-15 mg three or four times a day.
2. Moderate—10 mg-25 mg three or four times a day.
3. Severe—225 mg/day may be required.

DRUG INTERACTIONS Potentiation of drugs administered concurrently with MOBAN (molindone hydrochloride) has not been reported. Additionally, animal studies have not shown increased toxicity when MOBAN is given concurrently with representative members of three classes of drugs (i.e., barbiturates, chloral hydrate and antiparkinson drugs).

MANAGEMENT OF OVERDOSAGE Symptomatic, supportive therapy should be the rule.

Gastric lavage is indicated for the reduction of absorption of MOBAN (molindone hydrochloride) which is freely soluble in water.

Since the adsorption of MOBAN (molindone hydrochloride) by activated charcoal has not been determined, the use of this antidote must be considered of theoretical value.

Emesis in a comatose patient is contraindicated. Additionally, while the emetic effect of apomorphine is blocked by MOBAN in animals, this blocking effect has not been determined in humans.

A significant increase in the rate of removal of unmetabolized MOBAN (molindone hydrochloride) from the body by forced diuresis, peritoneal or renal dialysis would not be expected. (Only 2% of a single ingested dose of MOBAN is excreted unmetabolized in the urine.)

However, poor response of the patient may justify use of these procedures. While the use of laxatives or enemas might be based on general principles, the amount of unmetabolized MOBAN in feces is less than 1%. Extrapyramidal symptoms have responded to the use of diphenhydramine (Benadryl*) and the synthetic anticholinergic antiparkinson agents, (i.e., Artane*, Cogentin*, Akineton*).

HOW SUPPLIED As tablets in bottles with potencies and colors as follows:

100's and 1000's:
5 mg orange
10 mg lavender
25 mg light green

As a concentrate containing 20 mg molindone hydrochloride per ml in 4 oz. (120ml) bottles.

*Benadryl—Trademark, Parke Davis and Co.
*Artane—Trademark, Lederle Laboratories
*Cogentin—Trademark, Merck Sharp & Dohme
*Akineton—Trademark, Knoll Pharmaceutical Co.

DUPONT

CLORAZEPATE DIPOTASSIUM

Tranxene® CT

Ideal for short-term antianxiety therapy

Acts promptly...tapers gently at discontinuation

Tranxene goes to work in minutes

Nordiazepam uptake is rapid, with pharmacologic effects reported within 30 minutes.[1] Peak serum levels are attained within 1-2 hours after dosing.

Allows post-therapy adjustment time

When administration stops, nordiazepam serum levels taper at a gentle rate. This built-in taper may give your patients more time to adjust to cessation of therapy.[2]

1. Sedation reported in normal volunteers 30 minutes after dosing. Tranxene Drug Monograph 97-0185, p. 9, 1979.
2. The elimination kinetics of an agent can be closely defined, but these cannot at present be directly related to therapeutic or adverse effects.

Abbott Laboratories, North Chicago, IL 60064

0043331

Brief Summary

INDICATIONS — Symptomatic relief of anxiety and tension associated with anxiety disorders, other psychoneurotic disorders, transient situational disturbances, and functional or organic disorders. Symptomatic relief of acute alcohol withdrawal.

Effectiveness in long-term use (over 4 months) not assessed by systematic clinical studies. Physician should periodically reassess usefulness for each patient.

CONTRAINDICATIONS — Known hypersensitivity to the drug. Acute narrow angle glaucoma.

WARNINGS — Not for use in depressive neuroses or psychotic reactions. Caution patients against hazardous occupations requiring mental alertness, such as operating dangerous machinery including motor vehicles. Advise against simultaneous use of other CNS depressants, and caution patients that effects of alcohol may be increased. Not recommended for patients under 18. Nervousness, insomnia, irritability, diarrhea, muscle aches, and memory impairment have followed abrupt withdrawal from long-term high dosage. Withdrawal symptoms were reported after abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months. Use caution in patients having psychological potential for drug dependence (dependence has been observed in dogs and rabbits).

Pregnancy and Lactation: Minor tranquilizers should almost always be avoided first trimester. Consider possibility of pregnancy before initiating therapy. Patient should consult physician about discontinuation if she becomes pregnant or plans pregnancy. Do not give to nursing mothers.

PRECAUTIONS — Observe usual precautions in depression accompanying anxiety, or in patients with suicidal tendency, or those with impaired renal or hepatic function. Do periodic blood counts and liver function tests during prolonged therapy. Use small doses and gradual increments in the elderly or debilitated.

ADVERSE REACTIONS — Drowsiness, dizziness, various g.i. complaints, nervousness, blurred vision, dry mouth, headache, mental confusion, insomnia, transient skin rashes, fatigue, ataxia, genitourinary complaints, irritability, diplopia, depression, slurred speech, abnormal liver and kidney function, decreased hematocrit, decreased systolic blood pressure.

DOSAGE — ANXIETY—Usual daily dose 30 mg or less (start the elderly or debilitated at 7.5-15 mg). Adjust gradually within 15-60 mg daily range. Capsules and scored tablets: divided doses; or once daily h.s. (start patient at 15 mg). Single Dose Tablets, 22.5 mg (for patients stabilized on 7.5 mg t.i.d.) or 11.25 mg: once daily at any hour. ALCOHOL WITHDRAWAL—In divided doses: 1st day 30 mg initially, then 30-60 mg; 2nd day 45-90 mg; 3rd day 22.5-45 mg; 4th day 15-30 mg. Then taper to 15-7.5 mg daily, and discontinue as soon as stable.

INTERACTIONS — Potentiation may occur with ethyl alcohol, hypnotics, barbiturates, narcotics, phenothiazines, MAO inhibitors, other antidepressants.

OVERDOSAGE — Take general measures as for any CNS depressant.

SUPPLIED — Tranxene (clorazepate dipotassium) 3.75, 7.5, and 15 mg capsules and scored tablets. Tranxene-SD Half Strength 11.25 and Tranxene-SD 22.5 mg single dose tablets.

Acts promptly*...tapers gently at discontinuation

(CLORAZEPATE DIPOTASSIUM)

Tranxene® CIV

4306CB

Unexcelled choice for short-term management of anxiety

3.75, 7.5; and 15 mg capsules, scored tablets; 11.25 and 22.5 mg single dose tablets.

*Sedation reported in normal volunteers 30 minutes after dosing; Tranxene Drug Monograph, 97-0185, p. 9, 1979. See overleaf for brief summary.

SURROUNDED BY A WALL OF NDIFFERENCE

'STELAZINE' HELPS FIND A WAY THROUGH

The schizophrenic patient is often withdrawn, aloof and emotionally unresponsive. For such patients, 'Stelazine' provides effective, unsurpassed control of these and other psychotic symptoms.

Also important, 'Stelazine' can help patients participate in your therapeutic programs. 'Stelazine' usually does not cause excessive sedation and offers the convenience of b.i.d. dosage.

In fact, no other antipsychotic agent has demonstrated significantly greater overall effectiveness and significantly fewer adverse effects than 'Stelazine'.

'Stelazine'. A first choice for therapy.

Before prescribing, see complete prescribing information in SK&F Co. literature or PDR. The following is a brief summary.

Indications

Based on a review of this drug by the National Academy of Sciences—National Research Council and/or other information, FDA has classified the indications as follows:

Effective: For the management of the manifestations of psychotic disorders.

Possibly effective: To control excessive anxiety, tension and agitation as seen in neuroses or associated with somatic conditions.

'Stelazine' has not been shown effective in the management of behavioral complications in patients with mental retardation.

Final classification of the less-than-effective indications requires further investigation.

Contraindications: Comatose or greatly depressed states due to C.N.S. depressants; blood dyscrasias; bone marrow depression; liver damage.

Warnings: Generally avoid using in patients hypersensitive (e.g., blood dyscrasias, jaundice) to any phenothiazine. Caution patients about activities requiring alertness (e.g., operating vehicles or machinery), especially during the first few days' therapy.

Additive effect is possible with other C.N.S. depressants, including alcohol.

Use in pregnancy only when necessary for patient's welfare.

Precautions: Use cautiously in angina. Avoid high doses and parenteral administration when cardiovascular system is impaired. Antiemetic effect may mask signs of toxic drug overdosage or physical disorders. Prolonged administration of high doses may result in cumulative effects with severe C.N.S. or vasomotor symptoms. If retinal changes occur, discontinue drug. Agranulocytosis, thrombocytopenia, pancytopenia, anemia, cholestatic jaundice, liver damage have been reported.

Patients with a history of long-term therapy with 'Stelazine' and/or other neuroleptics should be evaluated periodically for possible adjustment or discontinuance of drug therapy. Neuroleptic drugs cause elevated prolactin levels that persist during chronic administration. Since approximately one-third of human breast cancers are prolactin-dependent in vitro, this elevation is of potential importance if neuroleptic drug administration is contemplated in a patient with a previously detected breast cancer. Neither clinical nor epidemiologic studies to date, however, have shown an association between the chronic administration of neuroleptic drugs and mammary tumorigenesis.

Adverse Reactions: Drowsiness, dizziness, skin reactions, rash, dry mouth, insomnia, amenorrhea, fatigue, muscular weakness, anorexia, lactation, blurred vision. Neuromuscular (extrapyramidal) reactions: motor restlessness, dystonias, pseudoparkinsonism, persistent tardive dyskinesia.

Other adverse reactions reported with Stelazine (trifluoperazine HCl, SK&F) or other phenothiazines: Some adverse effects are more frequent or intense in specific disorders (e.g., mitral insufficiency or pheochromocytoma).

Grand mal convulsions; altered cerebrospinal fluid proteins; cerebral edema; prolongation and intensification of the action of C.N.S. depressants, atropine, heat, and organophosphorus insecticides; nasal congestion, headache, nausea, constipation, obstipation, adynamic ileus, inhibition of ejaculation; reactivation of psychotic processes, catatonic-like states; hypotension (sometimes fatal); cardiac arrest; leukopenia, eosinophilia, pancytopenia, agranulocytosis, thrombocytopenic purpura; jaundice, biliary stasis; menstrual irregularities, galactorrhea, gynecomastia, false positive pregnancy tests; photosensitivity, itching, erythema, urticaria, eczema up to exfoliative dermatitis; asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions, peripheral edema; reversed epinephrine effect; hyperpyrexia; a systemic lupus erythematosus-like syndrome; pigmentary retinopathy; with prolonged administration of substantial doses, skin pigmentation, epithelial keratopathy, and lenticular and corneal deposits. EKG changes have been reported, but relationship to myocardial damage is not confirmed. Discontinue long-term, high-dose therapy gradually. NOTE: Sudden death in patients taking phenothiazines (apparently due to cardiac arrest or asphyxia due to failure of cough reflex) has been reported, but no causal relationship has been established.

Supplied: Tablets, 1 mg., 2 mg., 5 mg. and 10 mg., in bottles of 100; in Single Unit Packages of 100 (intended for institutional use only); Injection, 2 mg./ml.; and Concentrate (intended for institutional use only), 10 mg./ml.

A First Choice for Therapy

UNIVERSITY OF MEDICINE & D. LIBRARY

Continuous Offering: PKSAP IV

- NO REGISTRATION DEADLINES
- FLEXIBLE PARTICIPATION TIME
- CENTRAL SCORING SERVICES AVAILABLE (See Schedule Below)
- CME CATEGORY I APPLICABLE (if MCQ is centrally scored)

PSYCHIATRIC KNOWLEDGE AND SKILL SELF-ASSESSMENT PROGRAM

The Program

The PKSAP provides a comprehensive approach to self-study that focuses on recent advances in psychiatry. PKSAP-IV is completely revised and represents a considerable expansion over previous editions. The program includes 180 multiple-choice questions (MCQs) and 7 patient management problems (PMPs). For the first time, participants will receive a comprehensive syllabus of current knowledge in psychiatry to use in studying for the program as well as a critique book that explains the rationale for the answers. References will be provided for program follow-up.

Continuing Medical Education Credit

If a subscriber completes and returns the MCQ answer sheet for central scoring prior to the designated deadline, a maximum of forty (40) credit hours may be claimed in Category I. For those completing the program BUT do not return the MCQ answer sheets for scoring, hour-for-hour credit may be claimed in Category 5A, up to twenty-two (22) hour limit.

PERIODIC SCORING & REPORTING SCHEDULE:

If MCQ Answer Sheet Received By:	Performance Report Returned By:
November 28, 1980	February, 1981
March 31, 1981	June, 1981
July 31, 1981	October, 1981
November 27, 1981	February, 1982
March 31, 1982	June, 1982

You may register by completing the form below and submitting it with the appropriate fee to LETTERCOM - WASHINGTON, 310 Swann Avenue, Alexandria, VA. 22301. For further information, including group registrations (e.g. training programs), write the Office of Education, APA, 1700 18th Street, N.W., Washington, D.C. 20009.

THE AMERICAN JOURNAL OF PSYCHIATRY

CONTENTS Vol. 137, No. 11 November 1980

1325 Psychophysiologic Factors in Sudden Cardiac Death
Bernard Lown, Regis A. DeSilva, Peter Reich, and Benjamin J. Murawski

1336 Overview: The "Wife-Beater's Wife" Reconsidered
Elaine Hilberman

1348 Natural History of Male Psychological Health: IX. Empirical Evidence for Erikson's Model of the Life Cycle
George E. Vaillant and Eva Milofsky

1360 The Psychological Organization of Depression
Silvano Arieti and Jules R. Bemporad

1366 Medication Use and Deaths Attributed to Asphyxia Among Psychiatric Patients
Thomas J. Craig

1374 A Comparative Study of Borderline Patients in a Psychiatric Outpatient Clinic
Michael Sheehy, Lisa Goldsmith, and Edward Charles

1380 A Controlled Study of Self-Help Intervention for Widows
M.L.S. Vachon, W.A.L. Lyall, J. Rogers, K. Freedman-Letofsky, and S.J.J. Freeman

1385 Predicting Which Patients Will Be Discharged Against Medical Advice: A Pilot Study
Peter Steinglass, Charles E. Grantham, and Marc Hertzman

1390 Psychosis in a Peasant Society: Social Outcomes
Joseph Westermeyer

1395 The Role of Cholinergic Supersensitivity in the Medical Symptoms Associated with Withdrawal of Antipsychotic Drugs
Daniel J. Luchins, William J. Freed, and Richard Jed Wyatt

1399 A Clinic for the Impaired Elderly and Their Families
Burton V. Reifler and Carl Eisdorfer

1404 A Psychoanalytic Approach to a Therapeutic Impasse with an Impulsive Adolescent: Permission to Speak the Unspeakable
Axel Hoffer, Roger Goettsche, and Fay Linden

BRIEF COMMUNICATIONS

1410 Poor Premorbid Adjustment and CT Scan Abnormalities in Chronic Schizophrenia
Daniel R. Weinberger, Eleanor Cannon-Spoor, Steven G. Potkin, and Richard Jed Wyatt

1414 Pharmacokinetic Study of Lorazepam Overdosage
Marcia Divoll Allen, David J. Greenblatt, Yves LaCasse, and Richard I. Shader

1416 Seizures Terminable and Interminable with ECT
Richard D. Weiner, Michael R. Volow, Daniel T. Gianturco, and Jesse O. Cavenar, Jr.

1419 Modern Diagnosis Schizophrenia in Hospitalized Psychiatric Patients
Richard Ries, John Bokan, and Marc A. Schuckit

1422 Combined Monoamine Oxidase Inhibitor-Tricyclic Antidepressant Treatment: A Pilot Study
Kerrin White, Tom Pistole, and Jeffrey L. Boyd

1426 The Primal Scene: A Study of Prevalence
Alvin A Rosenfeld, Carole R. Smith, Anne O'Reilly Wenegrat, Wenda Brewster, and Diane K. Haavik

1429 An Indochinese Refugee Psychiatric Clinic: Culturally Accepted Treatment Approaches
J. David Kinzie, Kiet Anh Tran, Agatha Breckenridge, and Joseph D. Bloom

1433 Stress Response Syndrome Occurring After Delirium
Thomas B. Mackenzie and Michael K. Popkin

1436 Research Directions in Child Psychiatry
Irving Philips

1439 Documenting a Shortage of Psychiatrists: The Repair Shop Model
David J. Knesper

1443 From Supervisee to Supervisor: An Unexplored Aspect of the Psychiatrist's Education
Roger B. Granet, Thomas P. Kalman, and Michael H. Sacks

1446 Importance of Akinesia: Plasma Chlorpromazine and Prolactin Levels
Theodore Van Putten, Philip R.A. May, and Jeffery N. Wilkins

Information for Contributors

GENERAL POLICIES

Manuscripts are accepted for consideration with the understanding that they represent original material, have not been published previously, are not being considered for publication elsewhere, and have been approved by each author.

Copyright

The *Journal* requires express transfer of copyright to the American Psychiatric Association so that the author(s) and the Association are protected from misuse of copyrighted material. Authors of accepted papers will be asked to sign the following statement:

In consideration of the *American Journal of Psychiatry*'s taking action in reviewing and editing my submission [include title here] the author(s) undersigned hereby transfers, assigns, or otherwise conveys all copyright ownership to the American Psychiatric Association in the event that such work is published by the American Psychiatric Association.

Work done as part of an individual's duties as a federal employee is in the public domain. In such cases the following wording should be used:

The work described in [include title here] was done as part of my (our) employment with the federal government and is therefore in the public domain.

In addition, authors must obtain letters of permission from publishers for use of extensive quotations (more than 500 words) and of tables and figures that originally appeared elsewhere.

Patient Anonymity

Ethical as well as legal considerations require careful attention to the protection of a patient's anonymity in case reports and elsewhere. Identifying information such as names, initials, hospital numbers, and dates must be avoided. In addition, authors should disguise identifying information about a patient's characteristics and personal history.

Informed Consent

Manuscripts that report the results of experimental investigation with human subjects must include a statement that informed consent was obtained after the procedure(s) had been fully explained.

Review Process

Papers are reviewed by at least two experts to determine the originality, validity, and significance of content and conclusions. Authors will usually be advised within 3–4 months of the decision on their paper, although delays are sometimes unavoidable. Reviewers' comments will be returned with rejected manuscripts if they are judged to be useful to the authors. All reviewers remain anonymous.

SUBMISSION OF MANUSCRIPTS

Manuscripts should be submitted in triplicate to John C. Nemiah, M.D., Editor, *American Journal of Psychiatry*, 1700 Eighteenth St., N.W., Washington, D.C. 20009. All correspondence will be sent to the first-named author unless otherwise specified. Papers that are not accompanied by a cover letter indicating that the paper is intended for publication will not be reviewed until such a statement is received. On a separate sheet include the names and mailing addresses of any authors who are not members of APA; they will be sent a complimentary copy of the issue in which their article appears.

Authors will be notified as soon as possible of the receipt of their paper and the number assigned to it. **This number must be included in all further correspondence.** It is imperative that the corresponding author of submitted papers notify the *Journal* of changes of address.

Annual Meeting Papers

The *Journal* has first refusal rights for numbered papers accepted for presentation at the Association's annual meetings, although not all papers can be published in the *Journal*. Authors of annual meeting papers should follow instructions they will receive in a letter from the Editor before the meeting. Annual meeting papers may be submitted for review before the meeting only if they are in **final form,** i.e., are ready for review. Authors must **not** submit their papers before the meeting if they expect any substantive revisions due to discussion at the meeting, further research, etc. These papers are subject to the same peer review criteria as other submissions. Authors who wish to submit their papers elsewhere must secure permission from the Editor. The *Journal* will assign its own number to each paper received for review; **this number must appear in any further communications about the paper.**

Length

The length of submitted material should not exceed the following specifications unless a special arrangement has been made with the Editor. Regular articles—3,800 words or the equivalent **(no more than 15 double-spaced pages, including references, tables, and figures).** Brief Communications—2,500 words **(no more than 10 double-spaced pages, including references, tables, and figures).** Clinical and Research Reports—1,000 words, 10 references, 1 table (no figures are used). Letters to the Editor—500 words, 5 references. The number of words, tables, and figures should be noted on the title page.

TYPES OF ARTICLES

Overviews

Overview articles attempt to bring together important relevant information on a topic of general interest to psychiatry. They are usually written at the invitation of the Editor; authors who have ideas for overview articles are advised to check with the Editor to ensure that a similar work is not in preparation. Overviews should not exceed 7,500 words **(no more than 25 double-spaced pages—including tables and figures—and 100 references).** All overviews, including those written by invitation, are given the same peer review received by other papers.

Regular Articles and Brief Communications

The primary difference between these two types of papers is length. The "brief communication" designation does not imply less sophisticated or complete work: it merely means that the content can be expressed within the upper limit of 2,500 words. There is no difference in the review procedure or scheduling of these articles. Authors who submit unnecessarily long articles with redundancies and loose writing style will be asked to shorten them, which can delay publication. Authors should choose their words carefully, avoiding lengthy introductions containing material that is common knowledge, summaries that merely repeat the results, unnecessary tables, figures, or references, etc. Single case reports should be submitted as Clinical and Research Reports.

Clinical and Research Reports

This section contains very brief articles (maximum of 1,000 words, 10 references, 1 table, and **no figures**) reporting new research findings, including preliminary data from pilot studies, and case reports that 1) describe new syndromes, 2) cast a new light on established ones, 3) indicate a new therapeutic procedure of potential value, or 4) describe adverse effects or previously unreported complications of drugs or therapeutic interventions. Because of the stringent criteria for this section, authors can expect more rapid publication than is possible in other sections. Submitted papers that substantially exceed the stated maximum length or contain figures will be returned to the author unreviewed.

Prompt Publication Policy

Articles submitted for prompt publication can be of either regular of Brief Communication length. (A "prompt publication policy" is automatically in effect for Clinical and Research Reports.) These papers are given priority in scheduling; however, authors should be aware that the minimum publication time is four months. Prompt publication papers must meet stringent criteria of originality and be of major immediate importance to the field. Authors must state their reasons for wanting rapid review in a cover letter to the Editor. It is important to think carefully about the nature of the paper before requesting prompt publication; a paper may be delayed if it is submitted inappropriately.

Other Sections

Letters to the Editor. Brief letters (maximum of 500 words and 5 references) will be considered if they include the notation "for publication" in the upper right corner. Letters critical of an article published in the *Journal* will automatically be sent to the authors for reply. Because of space limitations not all letters can be printed. The *Journal* is unable to notify authors of receipt of letters or to return those not published. All letters are subject to editing. Letters must be typed **double-spaced** throughout on letter-size bond paper; two copies are required. Letters that are not typed appropriately or do not conform to *Journal* reference style will be returned to the author for revision.

Book Reviews. Books for review may be sent directly to the Book Review Editor, Nancy C. Andreasen, M.D., University of Iowa College of Medicine, 500 Newton Rd., Iowa City, Iowa 52240. Book reviews are usually solicited by the Book Review Editor. Authors interested in reviewing a particular book are urged to contact the editorial office to see if the Book Review Editor wishes the book to be reviewed and to ascertain whether it has been previously assigned to another reviewer.

TYPING AND ARRANGING THE PAPER

All parts of the manuscript, including case reports, quotations, references, and tables, must be **double-spaced** throughout. All manuscripts must be typed in upper- and lowercase on one side only of 22 × 28 cm (8½ × 11 inches) **nonerasable** bond paper. All 4 margins must be 3¾ cm (1½ inches). The manuscript should be arranged in the following order, with each numbered item beginning a new page: 1) title page, 2) précis, 3) text, 4) references, 5) tables, 6) footnotes to text, and 7) figure captions. All pages must be numbered, with the title page as number 1. Please consult the following section on *Journal* style specifications for criteria for each part of the paper.

STYLE SPECIFICATIONS

Title Page

Title. The title should be informative but as brief as possible. Headline style (declarative sentences) should be avoided. Abbreviations and acronyms are rarely used in titles.

By-line. Authors named in the by-line should be limited to principal researchers and/or writers; collaborators can be acknowledged in a footnote. Degrees (other than honorary or undergraduate degrees) should be included after the authors' names.

Previous presentation. If the paper has been presented orally, please give the name of the meeting, the place, and inclusive dates.

Author affiliations. Provide the department, institution, city, and state where the work was done. If multiple locations and authors were involved, indicate in parentheses which authors were affiliated with each institution. Provide a full address for the author who is to receive reprint requests.

Acknowledgments. Acknowledgments should be in a separate paragraph on the title page. Grant support should include the full name of the granting agency as well as the grant number. Individual acknowledgments should be as brief as possible. Acknowledgments of companies that supplied drugs are used only in the case of experimental drugs or those unavailable in this country.

Other requirements. The number of words, tables, and figures should appear in the upper right corner and a phone number for the corresponding author in the lower right.

Précis

The précis should be up to 100 words for regular articles and Brief Communications. (No précis is used in the Clinical and Research Reports section.) The précis should be a single paragraph using complete, connected sentences, active verbs, and the third person. In most cases, the précis replaces a summary.

Text

Headings and subheadings should be inserted at reasonable intervals in all types of papers. Footnotes to text material should be typed on a separate page at the end of the manuscript. Summaries are rarely desirable, although a final "Comment" or "Conclusions" section may be used. The body of the paper should be written in the active voice and first person where appropriate.

Statistics. Authors should be sure that statistics used are

both necessary and appropriate. Statistical tests should be described and a reference citation given if the tests are not generally known. It is not sufficient to say "differences between the groups were significant." In cases of lengthy complicated analyses, the authors may summarize results and indicate that details are available from them on request.

Abbreviations. All abbreviations (other than those for metric units) should be explained the first time they are used. Idiosyncratic abbreviations should be avoided: overuse of abbreviations may hinder rather than facilitate readability.

Drugs. Generic rather than trade names of drugs should be used; trade names may be given parenthetically if necessary.

Units of measurement. All measurements should be in metric units; standard abbreviations are used.

References

References should be restricted to closely pertinent material: a complete review of the literature is rarely desirable. **Accuracy of citation is the author's responsibility.** References should conform exactly to the original spelling, accents, punctuation, etc. Authors should be sure that all references listed have been cited in text; no bibliographies can be used.

References are numbered and listed by their order of appearance in text; the text citation is followed by the appropriate reference number in parentheses. Do **not** arrange the list alphabetically.

Personal communications, unpublished manuscripts, manuscripts submitted but not yet accepted, and similar unpublished items should not appear in the reference list. Such citations may be noted in text or in a footnote. It is the author's responsibility to obtain permission to refer to another individual's unpublished observations. Manuscripts that are actually "in press" may be cited as such in the reference list; the name of the journal must be included.

Type references in the style shown below, **double-spaced throughout** (not just a line between references). List up to three authors; designate one or more authors past the third "et al." Abbreviations of journal names should conform to the style used in *Index Medicus*; journals not indexed there should not be abbreviated.

1. Berne E: Principles of Group Treatment. New York, Oxford University Press, 1966, p 26
2. Blackwell B, Marley E, Price J, et al: Hypertensive interactions between monoamine oxidase inhibitors and foodstuffs. Br J Psychiatry 113:349-365, 1967
3. Jones AB: Long-term administration of tricyclic antidepressants: three-year follow-up. Am J Psychiatry (in press)
4. Smythe JCW (ed): Psychiatry and Human Values. Springfield, Ill, Charles C Thomas, 1971
5. Brosin H: Communication systems of the consultation process, in The Psychiatric Consultation. Edited by Mendel W, Solomon P. New York, Grune & Stratton, 1968

Tables

Tables should be self-explanatory and should supplement rather than duplicate text. Authors may be asked to delete tables that present data which could be given succinctly in text or repeat information in the Results section. Tables are generally reserved for data presentation and not used as lists or charts. They should be **double-spaced** and no wider than 120 typewriter characters, including spaces. Consult recent issues of the *Journal* for table style. Please note that no vertical rules or internal horizontal rules are used. It is usually desirable to give both numbers and percentages where applicable. All units of measurement must be specified within the table. Metric measurements are used in tables and throughout the text. Each table should be identified numerically and include a concise but descriptive title. **A copy of each table should be included in each copy of the manuscript.**

Figures

Figures should be used only for data that cannot be adequately presented in text or tabular form. Figures should be submitted as glossy prints **with one photocopy attached to each manuscript copy.** The author's name and the title of the paper should appear on a gummed label affixed to the back of each glossy. All figures should be able to withstand reduction to about 8 cm (3 1/4 inches). Authors are urged to consider carefully the necessity of figures; they may be asked to delete figures that repeat information availabile in text. It is often advisable to obtain professional assistance in the preparation of figures.

PROCESSING OF ACCEPTED MANUSCRIPTS

Authors will be notified of acceptance of their papers; papers will then be edited and sent to the first-named (or corresponding) author for corrections and answers to editorial queries. No galley proofs are sent to authors, so the edited manuscript should be read with extreme care. Prompt return of edited manuscripts is essential. Authors who expect to be away from their offices for a long period or who change address after notification of acceptance should so inform the *Journal* office.

Manuscripts are accepted with the understanding that the Editor has the right to make revisions aimed at greater conciseness, clarity, and conformity with *Journal* style.

PERMISSION TO REPRINT

Written permission to reprint material published in the *Journal* must be secured from the APA Publications Services Division, 1700 Eighteenth St., N.W., Washington, D.C. 20009; there is usually a charge for such permission, except in cases of nonprofit classroom or library reserve use by instructors and educational institutions, or of authors who wish to reprint their own material. Requests will be facilitated if they are accompanied by written permission from the author of the material.

REPRINTS

No reprints are furnished gratis. An order form for reprints will be sent to authors prior to publication of their papers. Reprints are usually mailed to authors about six weeks after publication of the article.

THE AMERICAN PSYCHIATRIC ASSOCIATION
1700 Eighteenth Street, N.W., Washington, D.C. 20009

OFFICERS 1980–1981

PSYCHOPHARMACOLOGY UPDATE

Jonathan O. Cole, M.D.

from

THE COLLAMORE PRESS

Medical Division of D.C. Heath and Company

For all practicing psychiatrists who wish to keep up to date on the uses of psychopharmacological agents and their potential side effects, this book offers a clear discussion of a range of available drugs. The information is practical and provides enough background for clinicians to practice psychopharmacology for the greatest benefit of patients. Newer agents such as lecithin, L-tryptophan, and fenfluramine are described. The book reviews treatment of such conditions as senile dementia and adult minimal brain dysfunction, and discusses such side effects of drugs as memory difficulties caused by tricyclic antidepressants, kidney changes due to lithium, and agranulocytosis resulting from antipsychotic drugs.

Table of contents: Part I. Drug Therapies: 1. Lithium Therapy: A Practical Review. 2. Tricyclic Antidepressant Blood Levels. 3. Drug Treatment of Anxiety, 4. Beta-Blocking Drugs in Psychiatry. 5. Drug Therapy of Adult Minimal Brain Dysfunction (MBD). 6. Fenfluramine. 7. Drugs and Senile Dementia. 8. Lecithin and Choline in Alzheimer Disease. Part II. Drug Side Effects: 9. Tardive Dyskinesia. 10. Agranulocytosis Revisited. 11. Lithium and the Kidney. 12. Memory Difficulty and Tricyclic Antidepressants.

208 pages **1980** **$14.95**
ISBN 0-669-03695-1 **LC 79-48064**

The Brown Schools: Specialists in Residential Treatment

Residential treatment has become highly specialized in the field of mental health. It is a specific treatment modality for those who need a totally planned and structured environment.

The Brown Schools has developed a wide range of professional services that can be utilized to implement an individually planned residential treatment program. The degree of structure and protection, the intensity of therapy, the methods of education and training are controlled and modified with the resident's changing needs.

Professionals in the areas of psychiatry, psychology, nursing, social work, education, prevocational training, speech pathology, and recreation have developed expertise in the specific area of residential treatment. Each service area is designed as a component of an integrated therapeutic milieu.

The three residential treatment centers of The Brown Schools provide complete programming for those in need of twenty-four hour care. Services are available for children, adolescents, and adults with emotional disturbance, mental retardation, and neurological impairment. Two small group homes in Austin provide for reintegration into the community and complement the services offered in the other centers. For information, write:

THE BROWN SCHOOLS

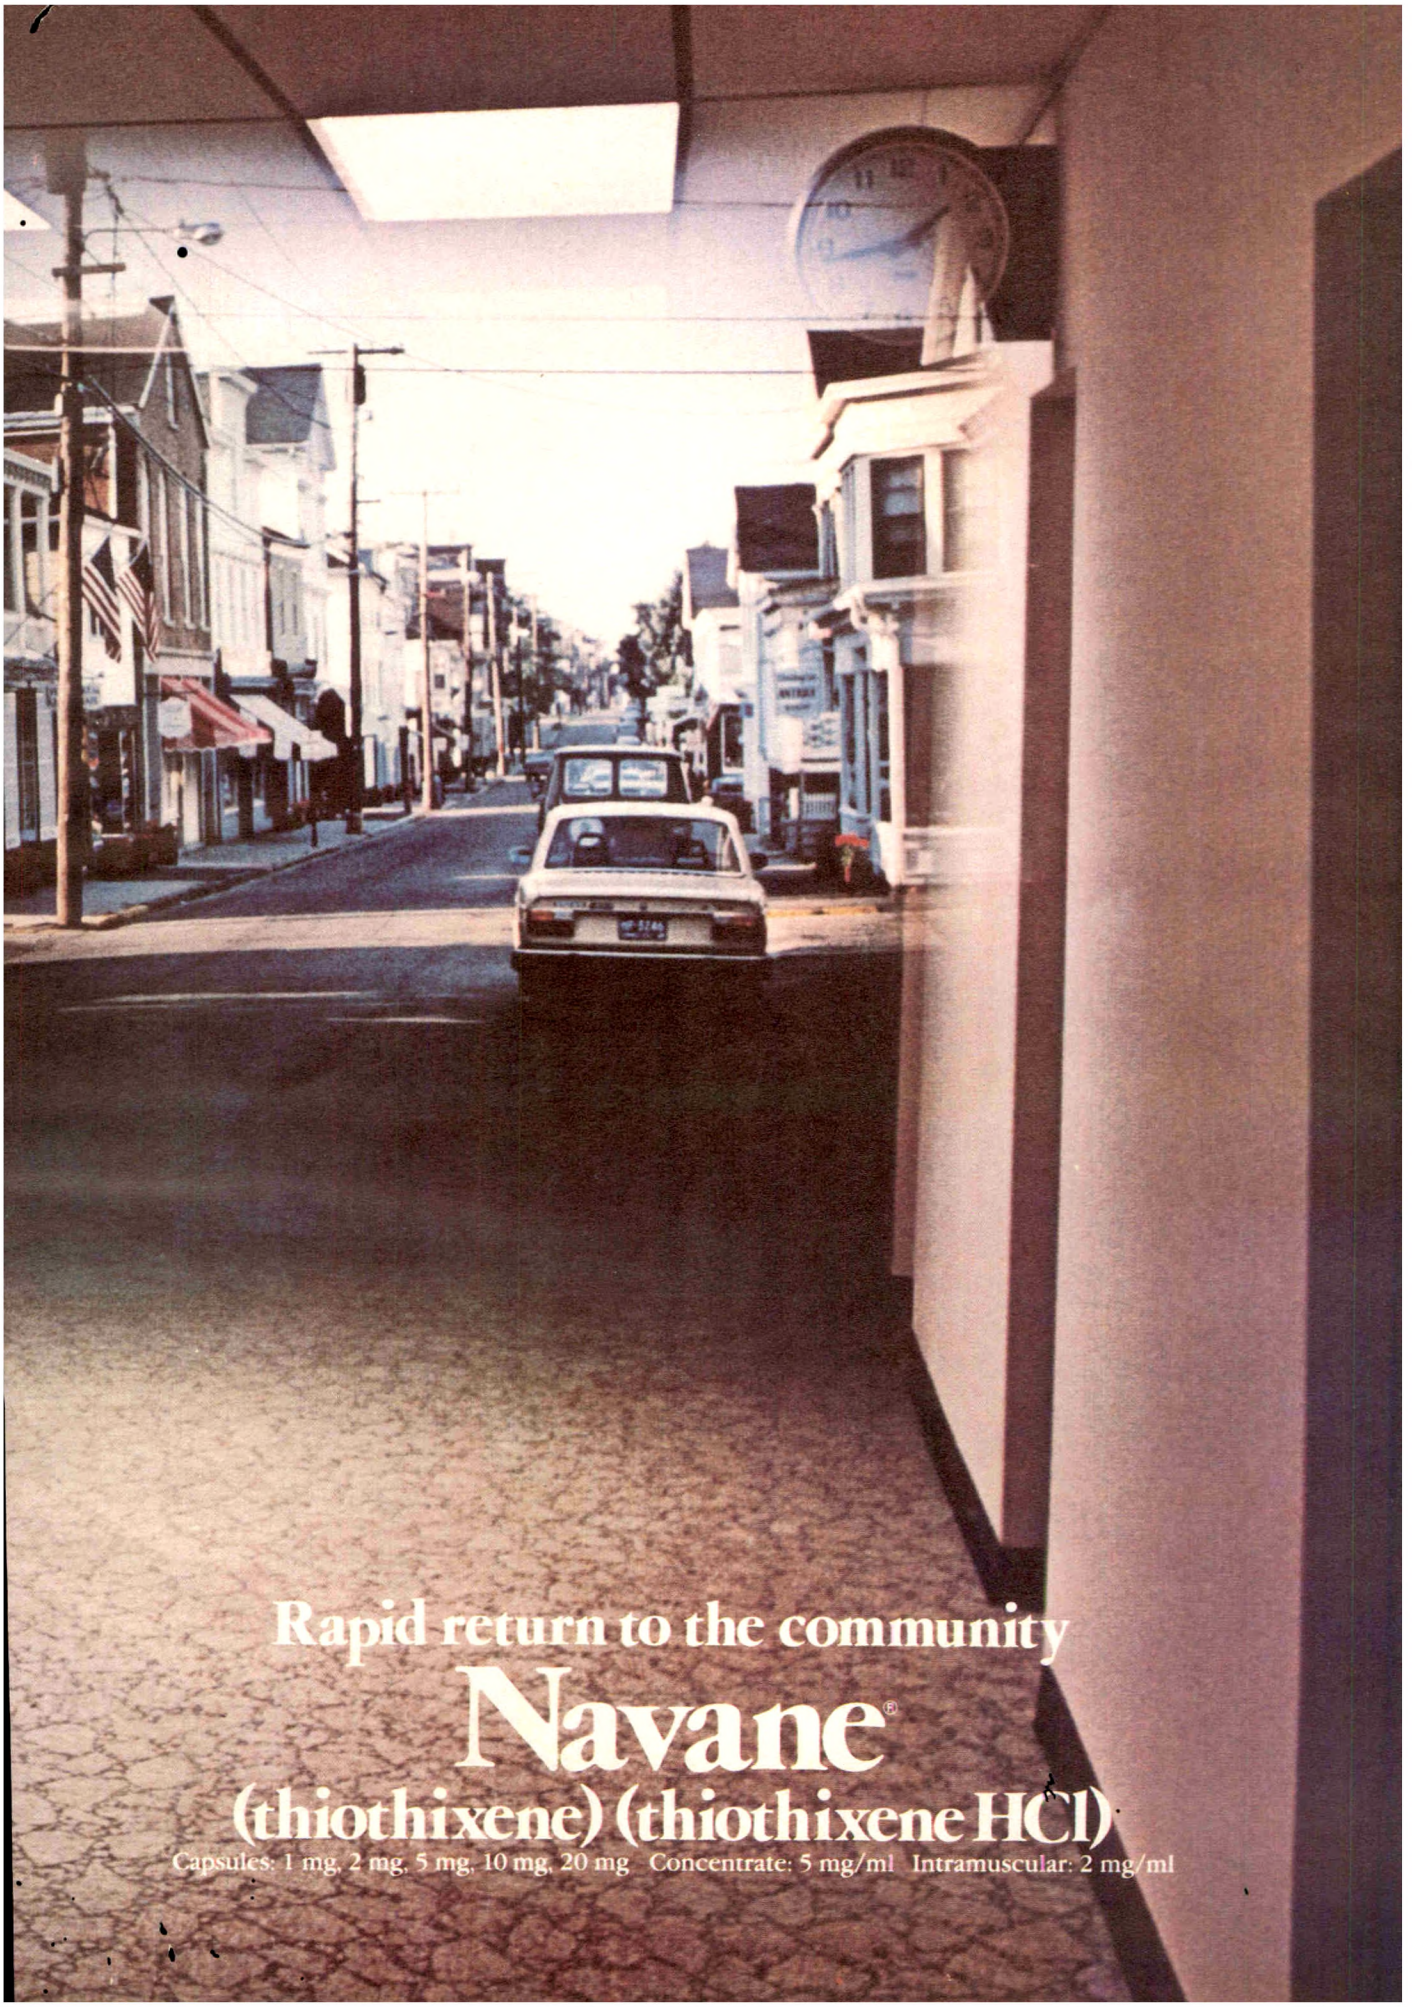
An equal opportunity employer. Psychiatric hospitals accredited by the Joint Commission on Accreditation of Hospitals.

The road back should be a one-way street...

Navane (thiothixene) has proved to be of significant benefit at each phase in rehabilitation of the patient with psychotic symptoms: from admission, through discharge, and beyond.

a rapid return to the community...

Navane achieves rapid relief of acutely disruptive symptoms and facilitates early discharge for most patients.[1] In excited, agitated psychotic patients, Navane has produced improvement within an hour, minimal symptomatology after three hours, and comparatively brief hospitalization for most patients.[1-3]



and continued long-term improvement...

On an outpatient basis, Navane exerts a significant long-term beneficial effect on patient functioning, especially in the areas of social and vocational adjustment in the community. Initial improvement is maintained with Navane and has been shown to increase over time.[1]

rarely compromised by adverse reactions...

With Navane, effectiveness is rarely compromised by oversedation or drowsiness.[4,5] Hypotensive crises and other cardiovascular reactions[4-8] are seldom reported. Anticholinergic side effects such as dry mouth or constipation are rare.[9] If extrapyramidal symptoms occur, they are usually readily controlled by dosage adjustments or antiparkinson agents.

For a brief summary of Navane prescribing information, including adverse reactions and contraindications, please see last page of this advertisement.

Rapid return to the community

Navane®

(thiothixene) (thiothixene HCl)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

Rapid return to the community

Navane® (thiothixene) (thiothixene hydrochloride)

Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg Concentrate: 5 mg/ml Intramuscular: 2 mg/ml

BRIEF SUMMARY OF PRESCRIBING INFORMATION
Navane® (thiothixene)
Capsules: 1 mg, 2 mg, 5 mg, 10 mg, 20 mg (thiothixene hydrochloride) Concentrate: 5 mg/ml, Intramuscular: 2 mg/ml

Contraindications. Navane (thiothixene) is contraindicated in patients with circulatory collapse, comatose states, central nervous system depression due to any cause, and blood dyscrasias. Navane is contraindicated in individuals who have shown hypersensitivity to the drug. It is not known whether there is a cross-sensitivity between the thioxanthenes and the phenothiazine derivatives, but this possibility should be considered.

Warnings. *Usage in Pregnancy*– Safe use of Navane during pregnancy has not been established. Therefore, this drug should be given to pregnant patients only when, in the judgment of the physician, the expected benefits from the treatment exceed the possible risks to mother and fetus. Animal reproduction studies and clinical experience to date have not demonstrated any teratogenic effects.

In the animal reproduction studies with Navane, there was some decrease in conception rate and litter size, and an increase in resorption rate in rats and rabbits, changes which have been similarly reported with other psychotropic agents. After repeated oral administration of Navane to rats (5 to 15 mg/kg/day), rabbits (3 to 50 mg/kg/day), and monkeys (1 to 3 mg/kg/day) before and during gestation, no teratogenic effects were seen. (See Precautions.)

Usage in Children– The use of Navane in children under 12 years of age is not recommended because safety and efficacy in the pediatric age group have not been established.

As is true with many CNS drugs, Navane may impair the mental and/or physical abilities required for the performance of potentially hazardous tasks such as driving a car or operating machinery, especially during the first few days of therapy. Therefore, the patient should be cautioned accordingly.

As in the case of other CNS-acting drugs, patients receiving Navane should be cautioned about the possible additive effects (which may include hypotension) with CNS depressants and with alcohol.

Precautions. An antiemetic effect was observed in animal studies with Navane; since this effect may also occur in man, it is possible that Navane may mask signs of overdosage of toxic drugs and may obscure conditions such as intestinal obstruction and brain tumor.

In consideration of the known capability of Navane and certain other psychotropic drugs to precipitate convulsions, extreme caution should be used in patients with a history of convulsive disorders or those in a state of alcohol withdrawal since it may lower the convulsive threshold. Although Navane potentiates the actions of the barbiturates, the dosage of the anticonvulsant therapy should not be reduced when Navane is administered concurrently.

Caution as well as careful adjustment of the dosage is indicated when Navane is used in conjunction with other CNS depressants other than anticonvulsant drugs.

Though exhibiting rather weak anticholinergic properties, Navane should be used with caution in patients who are known or suspected to have glaucoma, or who might be exposed to extreme heat, or who are receiving atropine or related drugs.

Use with caution in patients with cardiovascular disease.

Also, careful observation should be made for pigmentary retinopathy, and lenticular pigmentation (fine lenticular pigmentation has been noted in a small number of patients treated with Navane for prolonged periods). Blood dyscrasias (agranulocytosis, pancytopenia, thrombocytopenic purpura), and liver damage (jaundice, biliary stasis) have been reported with related drugs.

Undue exposure to sunlight should be avoided. Photosensitive reactions have been reported in patients on Navane.

Intramuscular Administration– As with all intramuscular preparations, Navane Intramuscular should be injected well within the body of a relatively large muscle. The preferred sites are the upper outer quadrant of the buttock (i.e., gluteus maximus) and the mid-lateral thigh.

The deltoid area should be used only if well developed, such as in certain adults and older children, and then only with caution to avoid radial nerve injury. Intramuscular injections should not be made into the lower and mid-thirds of the upper arm. As with all intramuscular injections, aspiration is necessary to help avoid inadvertent injection into a blood vessel.

Adverse Reactions. *Note:* Not all of the following adverse reactions have been reported with Navane (thiothixene). However, since Navane has certain chemical and pharmacologic similarities to the phenothiazines, all of the known side effects and toxicity associated with phenothiazine therapy should be borne in mind when Navane is used.

Cardiovascular effects: Tachycardia, hypotension, lightheadedness, and syncope. In the event hypotension occurs, epinephrine should not be used as a pressor agent since a paradoxical further lowering of blood pressure may result. Nonspecific EKG changes have been observed in some patients receiving Navane. These changes are usually reversible and frequently disappear on continued Navane therapy. The incidence of these changes is lower than that observed with some phenothiazines. The clinical significance of these changes is not known.

CNS effects: Drowsiness, usually mild, may occur although it usually subsides with continuation of Navane therapy. The incidence of sedation appears similar to that of the piperazine group of phenothiazines, but less than that of certain aliphatic phenothiazines. Restlessness, agitation and insomnia have been noted with Navane (thiothixene). Seizures and paradoxical exacerbation of psychotic symptoms have occurred with Navane infrequently.

Hyperreflexia has been reported in infants delivered from mothers having received structurally related drugs.

In addition, phenothiazine derivatives have been associated with cerebral edema and cerebrospinal fluid abnormalities.

Extrapyramidal symptoms, such as pseudo-parkinsonism, akathisia, and dystonia have been reported. Management of these extrapyramidal symptoms depends upon the type and severity. Rapid relief of acute symptoms may require the use of an injectable antiparkinson agent. More slowly emerging symptoms may be managed by reducing the dosage of Navane and/or administering an oral antiparkinson agent.

Persistent Tardive Dyskinesia: As with all antipsychotic agents tardive dyskinesia may appear in some patients on long term therapy or may occur after drug therapy has been discontinued. The risk seems to be greater in elderly patients on high-dose therapy, especially females. The symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements). Sometimes these may be accompanied by involuntary movements of extremities.

There is no known effective treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms of this syndrome. It is suggested that all antipsychotic agents be discontinued if these symptoms appear.

Should it be necessary to reinstitute treatment, or increase the dosage of the agent, or switch to a different antipsychotic agent, the syndrome may be masked.

It has been reported that fine vermicular movements of the tongue may be an early sign of the syndrome and if the medication is stopped at that time, the syndrome may not develop.

Hepatic effects: Elevations of serum transaminase and alkaline phosphatase, usually transient, have been infrequently observed in some patients. No clinically confirmed cases of jaundice attributable to Navane have been reported.

Hematologic effects: As is true with certain other psychotropic drugs, leukopenia and leukocytosis, which are usually transient, can occur occasionally with Navane. Other antipsychotic drugs have been associated with agranulocytosis, eosinophilia, hemolytic anemia, thrombocytopenia and pancytopenia.

Allergic reactions: Rash, pruritus, urticaria, photosensitivity and rare cases of anaphylaxis have been reported with Navane. Undue exposure to sunlight should be avoided. Although not experienced with Navane, exfoliative dermatitis and contact dermatitis (in nursing personnel) have been reported with certain phenothiazines.

Endocrine disorders: Lactation, moderate breast enlargement and amenorrhea have occurred in a small percentage of females receiving Navane. If persistent, this may necessitate a reduction in dosage or the discontinuation of therapy. Phenothiazines have been associated with false positive pregnancy tests, gynecomastia, hypoglycemia, hyperglycemia, and glycosuria.

Autonomic effects: Dry mouth, blurred vision, nasal congestion, constipation, increased sweating, increased salivation, and impotence have occurred infrequently with Navane therapy. Phenothiazines have been associated with miosis, mydriasis, and adynamic ileus.

Other adverse reactions: Hyperpyrexia, anorexia, nausea, vomiting, diarrhea, increase in appetite and weight, weakness or fatigue, polydipsia and peripheral edema.

Although not reported with Navane, evidence indicates there is a relationship between phenothiazine therapy and the occurrence of a systemic lupus erythematosus-like syndrome.

NOTE: Sudden deaths have occasionally been reported in patients who have received certain phenothiazine derivatives. In some cases the cause of death was apparently cardiac arrest or asphyxia due to failure of the cough reflex. In others, the cause could not be determined nor could it be established that death was due to phenothiazine administration.

Dosage and Administration. Dosage of Navane should be individually adjusted depending on the chronicity and severity of the condition. In general, small doses should be used initially and gradually increased to the optimal effective level, based on patient response.

Some patients have been successfully maintained on once-a-day Navane therapy.

Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

Navane Intramuscular Solution–For Intramuscular Use Only. Where more rapid control and treatment of acute behavior is desirable, the intramuscular form of Navane may be indicated. It is also of benefit where the very nature of the patient's symptomatology, whether acute or chronic, renders oral administration impractical or even impossible.

For treatment of acute symptomatology or in patients unable or unwilling to take oral medication, the usual dose is 4 mg of Navane Intramuscular administered 2 to 4 times daily. Dosage may be increased or decreased depending on response. Most patients are controlled on a total daily dosage of 16 to 20 mg. The maximum recommended dosage is 30 mg/day. An oral form should supplant the injectable form as soon as possible. It may be necessary to adjust the dosage when changing from the intramuscular to oral dosage forms. Dosage recommendations for Navane (thiothixene) Capsules and Concentrate appear in the following paragraphs.

Navane Capsules; Navane Concentrate– In milder conditions, an initial dose of 2 mg three times daily. If indicated, a subsequent increase to 15 mg/day total daily dose is often effective.

In more severe conditions, an initial dose of 5 mg twice daily.

The usual optimal dose is 20 to 30 mg daily. If indicated, an increase to 60 mg/day total daily dose is often effective. Exceeding a total daily dose of 60 mg rarely increases the beneficial response.

Overdosage. Manifestations include muscular twitching, drowsiness, and dizziness. Symptoms of gross overdosage may include CNS depression, rigidity, weakness, torticollis, tremor, salivation, dysphagia, hypotension, disturbances of gait, or coma.

Treatment: Essentially symptomatic and supportive. For Navane oral, early gastric lavage is helpful. For Navane oral and Intramuscular, keep patient under careful observation and maintain an open airway, since involvement of the extrapyramidal system may produce dysphagia and respiratory difficulty in severe overdosage. If hypotension occurs, the standard measures for managing circulatory shock should be used (I.V. fluids and/or vasoconstrictors).

If a vasoconstrictor is needed, levarterenol and phenylephrine are the most suitable drugs. Other pressor agents, including epinephrine, are not recommended, since phenothiazine derivatives may reverse the usual pressor action of these agents and cause further lowering of blood pressure.

If CNS depression is present, recommended stimulants include amphetamine, dextroamphetamine, or caffeine and sodium benzoate. Stimulants that may cause convulsions (e.g. picrotoxin or pentylenetetrazol) should be avoided. Extrapyramidal symptoms may be treated with antiparkinson drugs.

There are no data on the use of peritoneal or hemodialysis, but they are known to be of little value in phenothiazine intoxication.

How Supplied. Navane (thiothixene) is available as capsules containing 1 mg, 2 mg, 5 mg, and 10 mg of thiothixene in bottles of 100, 1,000, and unit-dose pack of 100 (10 x 10's). Navane is also available as capsules containing 20 mg of thiothixene in bottles of 100, 500, and unit-dose pack of 100 (10 x 10's).

Navane (thiothixene hydrochloride) Concentrate is available in 120 ml (4 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, 5 mg, 6 mg, 8 mg, and 10 mg, and in 30 ml (1 oz.) bottles with an accompanying dropper calibrated at 2 mg, 4 mg, and 5 mg. Each ml contains thiothixene hydrochloride equivalent to 5 mg of thiothixene. Contains alcohol, U.S.P. 7.0% v/v (small loss unavoidable).

Navane (thiothixene hydrochloride) Intramuscular solution is available in a 2 ml amber glass vial in packages of 10 vials. Each ml contains thiothixene hydrochloride equivalent to 2 mg of thiothixene, dextrose 5% w/v, benzyl alcohol 0.9% w/v, and propyl gallate 0.02% w/v.

Everyone Knows He's a Pillar of Strength in the Community.

You Know He's an Alcoholic.

You've seen what stress can do to people: everything from ulcers and high blood pressure, to a sense of isolation or a broken family.

You've also witnessed another consequence of stress: dependence on alcohol or drugs.

If some of your patients have drinking or drug problems, you should know about Fenwick Hall, a unique treatment facility near Charleston, S.C.

Fenwick Hall was established by Dr. Morris Chafetz, founding director of the National Institute on Alcoholism and Alcohol Abuse and a leading authority on alcohol and drug dependence.

Fenwick Hall's carefully designed, highly individualized treatment is based on the needs Dr. Chafetz perceived during his 25 years of experience with both patients and programs.

Rather than treating only symptoms, Fenwick Hall's approach focuses on every facet of the individual. In addition to complete detoxification capabilities and highly qualified professionals delivering a superior program of therapy, counseling and education, Fenwick Hall provides recreational options such as tennis courts, a sauna and whirlpool bath and an indoor swimming pool.

Occupying a recently restored 18th-century estate, Fenwick Hall offers unusually elegant accommodations and a tranquility conducive to the growth of self-awareness and the restoration of well-being.

When individuals leave Fenwick Hall, they are able to return to their careers and homes, fortified with healthier ways of coping with the stress and struggles of daily life.

For further information, please write for our color brochure, or call John Magill, Executive Director.

THE DANGEROUS PATIENT

Special Issue of *Psychiatric Quarterly*

Compiled by leading authorities in the fields of mental health and criminal justice, this work studies a perplexing, and often controversial, issue—the psychiatric patient who is prone to violence. Efforts to define and clarify this subject, recognize past errors, and provide effective treatment for the dangerous patient are offered. From the perspectives of criminal justice and psychiatry, certain key questions are scrutinized.

STUDIES IN NON-DETERMINISTIC PSYCHOLOGY

Volume V, New Directions in Psychotherapy Series
Series Editor: Paul T. Olsen, Ph.D.
An Official Publicaton of the National Institute for Psychotherapies

The impact of contemporary physics in the West and the acausal, non-deterministic philosophies of the Orient have revolutionized many principles of Western psychology and psychotherapy. In this volume, David Bohm, Kenneth Phillips, David Shamberg, Gerald Epstein, Swami Dayananda and other authorities present the theories of non-deterministic psychology while exploring its relationship to modern Western science and the meditative techniques of the East.

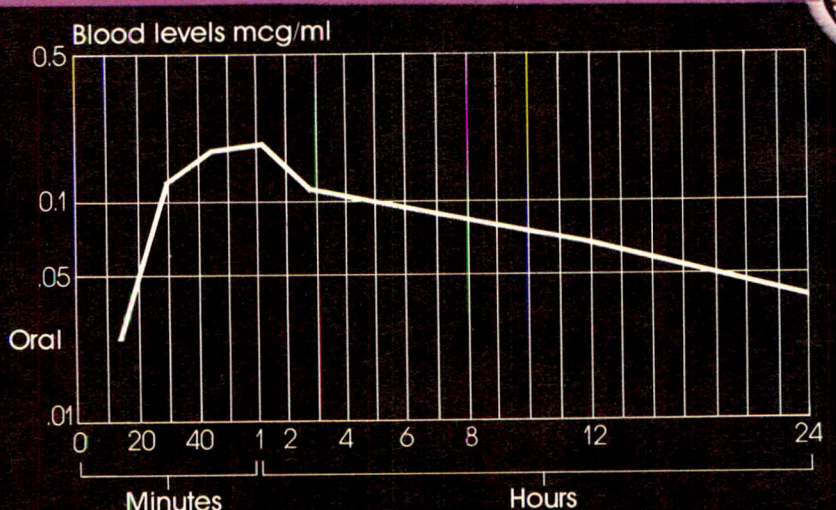
THE ASSESSMENT OF SEXUAL AND MARITAL FUNCTION



Special Issue of *Journal of Sex and Marital Therapy*

The scientific understanding of human sexuality depends upon the development of methods of measurement to gather, quantify and analyze information from individuals and groups. This book presents a concise overview of psychometric instruments for the study of sexual activity and marital interaction.

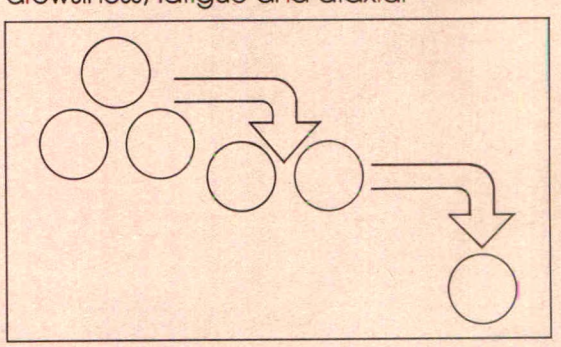
HUMAN SCIENCES PRESS
72 FIFTH AVENUE, NEW YORK, N.Y. 10011

Fast-in

24-hour blood level curve of 10-mg oral dose of diazepam in a single healthy subject.



Smooth-out

Smooth: Avoids sudden symptom breakthrough Because of its fast and complete absorption, peak blood levels of Valium (diazepam/Roche) are achieved in 60 to 90 minutes after a single dose for a rapid initial calming effect. Typically, with an appropriate dosage regimen (e.g., 5 mg *t.i.d.*) Valium builds in a uniform and predictable way to a steady-state level within 5-7 days, without accumulating beyond. With Valium the excretion rate is similarly consistent and predictable. When pharmacologic support is no longer needed, the overlapping half-lives of diazepam and its metabolites insure a gradual elimination process. Because metabolites of short-acting benzodiazepines are inactive, blood levels of these drugs decrease more rapidly without benefit of a tapering effect.

Consistent therapeutic effect even when an occasional dose is omitted Once steady-state is achieved, sudden symptom breakthrough is highly unlikely, even if a dose is forgotten or skipped. That's because the half-life of Valium—27-37 hours—provides the advantage of self-tapering action, complementing your gradual reduction of the patient's dosage and smoothing his transition to independent coping.

To discontinue smoothly... Gradual discontinuation of medication—while rarely necessary after short-term therapy—*is* good medical practice in patients who have received high doses for extended periods. When dosage is tapered, untoward side effects can be avoided. Throughout therapy, in fact, side effects are infrequent with Valium and are seldom more serious than drowsiness, fatigue and ataxia.

Before prescribing, please see summary of product information on following page. ROCHE®

2-mg, 5-mg, 10-mg scored tablets

Valium®

Smooth transition to independent coping

diazepam/Roche ℞

Valium®
diazepam/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Management of anxiety disorders, or short-term relief of symptoms of anxiety; symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not for sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow angle glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

***Usage in Pregnancy:* Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice, periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. to q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

Supplied: Valium® (diazepam/Roche) Tablets, 2 mg, 5 mg and 10 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available in trays of 10.

A PSYCHIATRIC GLOSSARY
Fifth Edition

Order your copy of the fifth edition of A PSYCHIATRIC GLOSSARY now!

The Glossary has been revised and updated by a Subcommittee of APA's Joint Commission on Public Afairs. It contains current terminology in psychiatry and incorporates the revised nomenclature of DSM III.

A useful, easy-to-use source of information for

—physicians and lawyers

—social workers, psychologists, and nurses

—writers and editors

—teachers and students

Numerous new entries, a series of tables, and a list of abbreviations used in the mental health field are included. Why not order one or more copies of A PSYCHIATRIC GLOSSARY now??

Please send me _____ copies of a PSYCHIATRIC GLOSSARY, 5th edition, paperback. Order number 142.
$5.95 each, 10-24 copies, $5.35 each; 25-99, $5.00 each; 100 or more, $4.75 each

☐ check or money order enclosed. All orders totalling $35 or less MUST be prepaid.

☐ bill me (orders over $35 ONLY). All invoices will include shipping and handling charges.

PLAN AHEAD! Order Your 1981 Appointment Books Now!!

The "week-at-a-glance" Appointment Book, published by the American Psychiatric Association, has been specifically developed to satisfy the needs of psychiatrists. It contains a comprehensive list of addresses and annual meeting dates of all major organizations and agencies of interest to psychiatrists. Members who have not tried this book in the past are urged to do so. It is returnable within 30 days for a full refund if not acceptable. (Returned copies must be received in saleable condition.)

The Pocket Size Appointment Book is also available and may be ordered in combination with the Desk Appointment Book.

Copies are available July 1980

DESK: $13.00
POCKET: $7.00
BOTH: $17.00
10% Discount for 10-99 copies
15% Discount for 100 copies or more
No discount available on set

WE'RE FIGHTING FOR YOUR LIFE

©1978, Pfizer Inc.

Artist Leonard Leff uses sculpture to express the painful depression he once experienced. He remembers it as "a lowering of the flame of life. My energies ebbed, my will to live decreased, and I found myself retreating from the activities of life to a more introverted existence."

WHEN DEPRESSION EXPRESSES ITSELF

SINEQUAN®
(DOXEPIN HCl)

ANTIDEPRESSANT EFFECTIVENESS with convenient once-a-day *h.s.* dosage*

150-MG CAPSULE†

Also available in:
100-mg, 75-mg, 50-mg, 25-mg, 10-mg CAPSULES and ORAL CONCENTRATE, 10 mg/ml, in 120-ml (4-oz) bottles

*The total daily dosage of Sinequan, up to 150 mg, may be administered on a once-a-day schedule without loss of effectiveness.

† The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

UNIVERSITY OF TEXAS COLLEGE OF MEDICINE LIBRARY

See Brief Summary on next page for information on contraindications, warnings, precautions and adverse reactions.

ANTIDEPRESSANT EFFECTIVENESS

SINEQUAN®
(DOXEPIN HCl)

150-mg CAPSULE*

*The 150-mg capsule strength is intended for maintenance therapy only and is not recommended for initiation of treatment.

CONVENIENT ONCE-A-DAY *h.s.* DOSAGE

which may improve patient compliance. The total daily dosage, up to 150 mg per day, may be given on a once-a-day schedule without loss of effectiveness. Sinequan may also be given on a divided dosage schedule, up to 300 mg per day.

PROMINENT SEDATIVE EFFECT

which may help to relieve the difficulty in falling and staying asleep, and the early-morning awakening often associated with depression.

ESTABLISHED ANTIANXIETY ACTIVITY

to help alleviate the anxiety which often accompanies clinical depression.

USUALLY WELL TOLERATED

At doses up to 150 mg per day, Sinequan does not generally affect the antihypertensive activity of guanethidine and related compounds. Tachycardia and hypotension have been reported occasionally. Drowsiness is the most commonly observed side effect. Dry mouth, blurred vision, constipation and urinary retention have been reported.

EXTENDED RANGE OF DOSAGE STRENGTHS

for flexibility in individualizing therapy.

BRIEF SUMMARY
SINEQUAN® (doxepin HCl) Capsules/Oral Concentrate

Contraindications. Contraindicated in individuals who have shown hypersensitivity to the drug, and in patients with glaucoma or a tendency to urinary retention. These disorders should be ruled out, particularly in older patients. Possibility of cross sensitivity with other dibenzoxepines should be kept in mind.

Warnings. The once-a-day dosage regimen of SINEQUAN (doxepin HCl) in patients with intercurrent illness or patients taking other medications should be carefully adjusted. This is especially important in patients receiving other medications with anticholinergic effects.

Usage in Geriatrics: The use of SINEQUAN on a once-a-day dosage regimen in geriatric patients should be adjusted carefully based on the patient's condition.

Usage in Pregnancy: Reproduction studies performed in animals have shown no evidence of harm to the animal fetus. Since there is no experience in pregnant women receiving this drug, safety in pregnancy has not been established. There are no data with respect to the secretion of the drug in human milk and its effect on the nursing infant.

Usage in Children: Usage in children under 12 years of age is not recommended because safe conditions for its use have not been established.

MAO Inhibitors: Serious side effects and even death have been reported following the concomitant use of certain drugs with MAO inhibitors. Therefore, MAO inhibitors should be discontinued at least two weeks prior to the cautious initiation of therapy with this drug. The exact length of time may vary and is dependent upon the particular MAO inhibitor being used, the length of time it has been administered and the dosage involved.

Usage with Alcohol: It should be borne in mind that alcohol ingestion may increase the danger inherent in any intentional or unintentional SINEQUAN overdosage. This is especially important in patients who may use alcohol excessively.

Precautions. Since drowsiness may occur with the use of this drug, patients should be warned of that possibility and cautioned against driving a car or operating dangerous machinery while taking this drug.

Patients should also be cautioned that their response to alcohol may be potentiated.

Since suicide is an inherent risk in any depressed patient, and may remain so until significant improvement has occurred, patients should be closely supervised during the early course of therapy. Prescriptions should be written for the smallest feasible amount.

Should increased symptoms of psychosis or shift to manic symptomatology occur, it may be necessary to reduce dosage or add a major tranquilizer to the dosage regimen.

Adverse Reactions. NOTE: Some of the adverse reactions noted below have not been specifically reported with SINEQUAN use. However, due to the close pharmacological similarities among the tricyclics, the reactions should be considered when prescribing SINEQUAN.

Anticholinergic Effects: Dry mouth, blurred vision, constipation, and urinary retention have been reported. If they do not subside with continued therapy, or become severe, it may be necessary to reduce the dosage.

Central Nervous System Effects: Drowsiness is the most commonly noticed side effect. This tends to disappear as therapy is continued. Other infrequently reported CNS side effects are confusion, disorientation, hallucinations, numbness, paresthesias, ataxia, and extrapyramidal symptoms and seizures.

Cardiovascular: Cardiovascular effects including hypotension and tachycardia have been reported occasionally.

Allergic: Skin rash, edema, photosensitization, and pruritus have occasionally occurred.

Hematologic: Eosinophilia has been reported in a few patients. There have been occasional reports of bone marrow depression manifesting as agranulocytosis, leukopenia, thrombocytopenia, and purpura.

Gastrointestinal: Nausea, vomiting, indigestion, taste disturbances, diarrhea, anorexia, and aphthous stomatitis have been reported. (See anticholinergic effects.)

Endocrine: Raised or lowered libido, testicular swelling, gynecomastia in males, enlargement of breasts and galactorrhea in the female, raising or lowering of blood sugar levels have been reported with tricyclic administration.

Other: Dizziness, tinnitus, weight gain, sweating, chills, fatigue, weakness, flushing, jaundice, alopecia, and headache have been occasionally observed as adverse effects.

Dosage and Administration. For most patients with illness of mild to moderate severity, starting daily dose of 75 mg is recommended. Dosage may subsequently be increased decreased at appropriate intervals and according to individual response. The usual optimu dose range is 75 mg/day to 150 mg/day.

In more severely ill patients higher doses may be required with subsequent gradual increase 300 mg/day if necessary. Additional therapeutic effect is rarely to be obtained by exceeding dose of 300 mg/day.

In patients with very mild symptomatology or emotional symptoms accompanying organ disease, lower doses may suffice. Some of these patients have been controlled on doses as lo as 25-50 mg/day.

The total daily dosage of SINEQUAN (doxepin HCl) may be given on a divided or once-a-d dosage schedule. If the once-a-day schedule is employed the maximum recommended dose 150 mg/day. This dose may be given at bedtime. **The 150 mg capsule strength is intended f maintenance therapy only and is not recommended for initiation of treatment.**

Antianxiety effect is apparent before the antidepressant effect. Optimal antidepressant effe may not be evident for two to three weeks.

Overdosage.

A. Signs and Symptoms

1. Mild: Drowsiness, stupor, blurred vision, excessive dryness of mouth.

2. Severe: Respiratory depression, hypotension, coma, convulsions, cardiac arrhythmias a tachycardias.

Also: urinary retention (bladder atony), decreased gastrointestinal motility (paralytic ileu hyperthermia (or hypothermia), hypertension, dilated pupils, hyperactive reflexes.

B. Management and Treatment

1. Mild: Observation and supportive therapy is all that is usually necessary.

2. Severe: Medical management of severe SINEQUAN overdosage consists of aggressi supportive therapy. If the patient is conscious, gastric lavage, with appropriate precautions prevent pulmonary aspiration, should be performed even though SINEQUAN is rapidly absorb The use of activated charcoal has been recommended, as has been continuous gastric lava with saline for 24 hours or more. An adequate airway should be established in comatose pati and assisted ventilation used if necessary. EKG monitoring may be required for several da since relapse after apparent recovery has been reported. Arrhythmias should be treated with t appropriate antiarrhythmic agent. It has been reported that many of the cardiovascular and C symptoms of tricyclic antidepressant poisoning in adults may be reversed by the slow int venous administration of 1 mg to 3 mg of physostigmine salicylate. Because physostigmine rapidly metabolized, the dosage should be repeated as required. Convulsions may respond standard anticonvulsant therapy; however, barbiturates may potentiate any respiratory depr sion. Dialysis and forced diuresis generally are not of value in the management of overdosa due to high tissue and protein binding of SINEQUAN.

Supply. SINEQUAN is available as capsules containing doxepin HCl equivalent to: 10 mg, 75 r and 100 mg doxepin: bottles of 100, 1000, and unit-dose packages of 100 (10 x 10's). 25 mg a 50 mg doxepin: bottles of 100, 1000, 5000, and unit-dose packages of 100 (10 x 10's). 150 doxepin: bottles of 50, 500, and unit-dose packages of 100 (10 x 10's). SINEQUAN O Concentrate (10 mg/ml) is available in 120 ml bottles with an accompanying dropper calibrat at 5 mg, 10 mg, 15 mg, 20 mg, and 25 mg. Each ml contains doxepin HCl equivalent to 10 doxepin. Just prior to administration, SINEQUAN Oral Concentrate should be diluted w approximately 120 ml of water, whole or skimmed milk, or orange, grapefruit, tomato, prune pineapple juice. SINEQUAN Oral Concentrate is not physically compatible with a numbe carbonated beverages. For those patients requiring antidepressant therapy who are methadone maintenance, SINEQUAN Oral Concentrate and methadone syrup can be mi together with Gatorade®, lemonade, orange juice, sugar water, Tang®, or water; but not w grape juice. Preparation and storage of bulk dilutions is not recommended.

More detailed professional information available on request.

ROERIG Pfizer

A division of Pfizer Pharmaceuticals New York, New York 10017

The American Psychiatric Association
Introduces

An essential program for clinicians learning to incorporate and utilize DSM-III

THE DSM-III INSTITUTIONAL INSTRUCTION KIT

THE DSM-III INSTITUTIONAL INSTRUCTION KIT acquaints physicians and their staff with:

- the multiaxial evaluation method used to report the official DSM-III diagnosis
- the use of new diagnostic categories in making a differential diagnosis
- the use of criteria as guides in making psychiatric diagnosis for the most significant disorders in:

Affective Disorders
Schizophrenia and Related Psychotic Disorders
Anxiety, Dissociative, and Somatoform Disorders
Personality Disorders
Disorders Usually Arising in Childhood or Adolescence

PROGRAM COMPONENTS:
The Instructor's Kit for workshop leaders contains:

- videotape of nine clinical case simulations
- loose-leaf binder containing:
  - — 4 audiocassettes plus transcripts of original faculty presentations
  - — 39 slides complementing audiotaped presentations
  - — course syllabus, patient histories, worksheets, references
  - — DSM-III diagnosis for each of 30 patient histories

The Participant's Kit for individual workshop members includes:

- course syllabus
- patient histories
- worksheets

CONTINUING MEDICAL EDUCATION (CME) CREDIT:
These learning materials can be used by educational organizations or institutions in the development of, or as an adjunct to, a variety of learning programs for CME Category 1, 2, or 5.

breaking
through

In marked agitation with depression symptomatic relief may make the patient more accessible and responsive.

Rapid relief of marked agitation in many patients
The tranquilizer component alleviates symptoms of agitation and anxiety within a few days, without apparent dulling of mental acuity. Hypnotic effects from the tranquilizer component appear to be minimal, particularly in patients permitted to remain active. However, TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks.

Highly effective antidepressant action
The antidepressant component relieves symptoms of depression such as poor concentration and feelings of hopelessness as well as early morning awakening; adequate relief of symptoms may take a few weeks or even longer.

Helps break barriers to psychotherapy
As symptoms are relieved, many patients often communicate more effectively, become more cooperative, and are able to return to normal daily activities.

More prescribing convenience
There are now *five* tablet strengths of TRIAVIL for ease of dosage adjustment. For many patients with agitation and depression, you can now initiate therapy with one TRIAVIL® 4-50, containing 4 mg perphenazine and 50 mg amitriptyline HCl, b.i.d. The regimen is simple, economical, and may well enhance patient compliance.

Treatment with TRIAVIL—a balanced view:
TRIAVIL is contraindicated in CNS depression from drugs, in the presence of evidence of bone marrow depression, and in patients hypersensitive to phenothiazines or amitriptyline. It should not be used during the acute recovery phase following myocardial infarction or in patients who have received an MAOI within two weeks. Patients with cardiovascular disorders should be watched closely. Not recommended in children or during pregnancy. TRIAVIL may impair mental and/or physical abilities required for performance of hazardous tasks and may enhance the response to alcohol. Antiemetic effect may obscure toxicity due to overdosage of other drugs or mask other disorders. The possibility of suicide in depressed patients remains until significant remission occurs. Such patients should not have access to large quantities of the drug. Hospitalize as soon as possible any patient suspected of having taken an overdose.

For marked agitation with depression

dual-action **Triavil®**

containing perphenazine and amitriptyline HCl

MSD
MERCK SHARP & DOHME

Copyright © 1979 by Merck & Co., Inc.

Please see following page for a brief summary of prescribing information.

More dosage strengths than any other formulation containing a tranquilizer and an antidepressant

dual-action Triavil®

containing perphenazine and amitriptyline HCl

Available:
TRIAVIL® 2-25: Each tablet contains
2 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 2-10: Each tablet contains
2 mg perphenazine and 10 mg amitriptyline HCl.
TRIAVIL® 4-50: Each tablet contains
4 mg perphenazine and 50 mg amitriptyline HCl.
TRIAVIL® 4-25: Each tablet contains
4 mg perphenazine and 25 mg amitriptyline HCl.
TRIAVIL® 4-10: Each tablet contains
4 mg perphenazine and 10 mg amitriptyline HCl.

CONTRAINDICATIONS: Central nervous system depression from drugs (barbiturates, alcohol, narcotics, analgesics, antihistamines); evidence of bone marrow depression; known hypersensitivity to phenothiazines or amitriptyline. Should not be given concomitantly with a monoamine oxidase inhibitor since hyperpyretic crises, severe convulsions, and deaths have occurred from such combinations. When used to replace a monoamine oxidase inhibitor, allow a minimum of 14 days to elapse before initiating therapy with TRIAVIL. Therapy should then be initiated cautiously with gradual increase in dosage until optimum response is achieved. Not recommended for use during acute recovery phase following myocardial infarction.

WARNINGS: TRIAVIL should not be given concomitantly with guanethidine or similarly acting compounds since TRIAVIL may block the antihypertensive action of such compounds. Use cautiously in patients with history of urinary retention, angle-closure glaucoma, increased intraocular pressure, or convulsive disorders. Dosage of anticonvulsive agents may have to be increased. In patients with angle-closure glaucoma, even average doses may precipitate an attack. Patients with cardiovascular disorders should be watched closely. Tricyclic antidepressants, including amitriptyline HCl, have been reported to produce arrhythmias, sinus tachycardia, and prolongation of conduction time, particularly in high doses. Myocardial infarction and stroke have been reported with tricyclic antidepressant drugs. Close supervision is required for hyperthyroid patients or those receiving thyroid medication. May impair mental and/or physical abilities required for performance of hazardous tasks, such as operating machinery or driving a motor vehicle. TRIAVIL may enhance the response to alcohol and the effects of barbiturates and other CNS depressants. In patients who use alcohol excessively, potentiation may increase the danger inherent in any suicide attempt or overdosage. Not recommended in children or during pregnancy.

PRECAUTIONS: Suicide is a possibility in depressed patients and may remain until significant remission occurs. Such patients should not have access to large quantities of this drug.

Perphenazine: Should not be used indiscriminately. Use with caution in patients who have previously exhibited severe adverse reactions to other phenothiazines. Likelihood of some untoward actions is greater with high doses. Closely supervise with any dosage. The antiemetic effect of perphenazine may obscure signs of toxicity due to overdosage of other drugs or make more difficult the diagnosis of disorders such as brain tumor or intestinal obstruction. A significant, not otherwise explained, rise in body temperature may suggest individual intolerance to perphenazine, in which case discontinue.

If hypotension develops, epinephrine should not be employed, as its action is blocked and partially reversed by perphenazine. Phenothiazines may potentiate the action of central nervous system depressants (opiates, analgesics, antihistamines, barbiturates, alcohol) and atropine. In concurrent therapy with any of these, TRIAVIL should be given in reduced dosage. May also potentiate the action of heat and phosphorous insecticides. Neuroleptic drugs elevate prolactin levels; the elevation persists during chronic administration. Tissue culture experiments indicate that approximately one-third of human breast cancers are prolactin dependent *in vitro*, a factor of potential importance if the prescription of these drugs is contemplated in a patient with a previously detected breast cancer. Although disturbances such as galactorrhea, amenorrhea, gynecomastia, and impotence have been reported, the clinical significance of elevated serum prolactin levels is unknown for most patients. An increase in mammary neoplasms has been found in rodents after chronic administration of neuroleptic drugs. Neither clinical studies nor epidemiologic studies conducted to date, however, have shown an association between chronic administration of these drugs and mammary tumorigenesis; the available evidence is considered too limited to be conclusive at this time.

Amitriptyline: In manic-depressive psychosis, depressed patients may experience a shift toward the manic phase if they are treated with an antidepressant. Patients with paranoid symptomatology may have an exaggeration of such symptoms. The tranquilizing effect of TRIAVIL seems to reduce the likelihood of this effect. When amitriptyline HCl is given with anticholinergic agents or sympathomimetic drugs, including epinephrine combined with local anesthetics, close occur in patients taking tricyclic antidepressants in combination with anticholinergic-type drugs.

Caution is advised if patients receive large doses of ethchlorvynol concurrently. Transient delirium has been reported in patients who were treated with 1 g of ethchlorvynol and 75-150 mg of amitriptyline HCl.

Concurrent administration of amitriptyline HCl and electroshock therapy may increase the hazards associated with such therapy. Such treatment should be limited to patients for whom it is essential. Discontinue several days before elective surgery if possible. Elevation and lowering of blood sugar levels have both been reported. Use with caution in patients with impaired liver function.

ADVERSE REACTIONS: Similar to those reported with either constituent alone.

Perphenazine: Extrapyramidal symptoms (opisthotonus, oculogyric crisis, hyperreflexia, dystonia, akathisia, acute dyskinesia, ataxia, parkinsonism) have been reported and can usually be controlled by the concomitant use of effective antiparkinsonian drugs and/or by reduction in dosage, but sometimes persist after discontinuation of the phenothiazine.

Tardive dyskinesia may appear in some patients on long-term therapy or may occur after drug therapy with phenothiazines and related agents has been discontinued. The risk appears to be greater in elderly patients on high-dose therapy, especially females. Symptoms are persistent and in some patients appear to be irreversible. The syndrome is characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw. Involuntary movements of the extremities sometimes occur. There is no known treatment for tardive dyskinesia; antiparkinsonism agents usually do not alleviate the symptoms. It is advised that all antipsychotic agents be discontinued if the above symptoms appear. If treatment is reinstituted, or dosage of the particular drug increased, or another drug substituted, the syndrome may be masked. Fine vermicular movements of the tongue may be an early sign of the syndrome. The full-blown syndrome may not develop if medication is stopped when lingual vermiculation appears.

Other side effects are skin disorders (photosensitivity, itching, erythema, urticaria, eczema, up to exfoliative dermatitis); other allergic reactions (asthma, laryngeal edema, angioneurotic edema, anaphylactoid reactions); peripheral edema; reversed epinephrine effect; hyperglycemia; endocrine disturbances (lactation, galactorrhea, gynecomastia, disturbances of menstrual cycle); altered cerebrospinal fluid proteins; paradoxical excitement; hypertension, hypotension, tachycardia, and ECG abnormalities (quinidine-like effect); reactivation of psychotic processes; catatonic-like states; autonomic reactions, such as dry mouth or salivation, headache, anorexia, nausea, vomiting, constipation, obstipation, urinary frequency or incontinence, blurred vision, nasal congestion, and a change in pulse rate; other adverse reactions reported with various phenothiazine compounds, but not with perphenazine, include grand mal convulsions, cerebral edema, polyphagia, pigmentary retinopathy, photophobia, skin pigmentation, and failure of ejaculation.

The phenothiazine compounds have produced blood dyscrasias (pancytopenia, thrombocytopenic purpura, leukopenia, agranulocytosis, eosinophilia); and liver damage (jaundice, biliary stasis).

Pigmentation of the cornea and lens has been reported to occur after long-term administration of some phenothiazines. Although it has not been reported in patients receiving TRIAVIL, the possibility that it might occur should be considered.

Hypnotic effects, lassitude, muscle weakness, and mild insomnia have also been reported.

Amitriptyline: Note: Listing includes a few reactions not reported for this drug, but which have occurred with other pharmacologically similar tricyclic antidepressant drugs and must be considered when amitriptyline is administered. *Cardiovascular:* Hypotension; hypertension; tachycardia; palpitation; myocardial infarction; arrhythmias; heart block; stroke. *CNS and Neuromuscular:* Confusional states; disturbed concentration; disorientation; delusions; hallucinations; excitement; anxiety; restlessness; insomnia; nightmares; numbness, tingling, and paresthesias of the extremities; peripheral neuropathy; incoordination; ataxia; tremors; seizures; alteration in EEG patterns; extrapyramidal symptoms; tinnitus; syndrome of inappropriate ADH (antidiuretic hormone) secretion. *Anticholinergic:* Dry mouth; blurred vision; disturbance of accommodation; increased intraocular pressure; constipation; paralytic ileus; urinary retention; dilatation of urinary tract. *Allergic:* Skin rash; urticaria; photosensitization; edema of face and tongue. *Hematologic:* Bone marrow depression including agranulocytosis; leukopenia; eosinophilia; purpura; thrombocytopenia. *Gastrointestinal:* Nausea; epigastric distress; vomiting; anorexia; stomatitis; peculiar taste; diarrhea; parotid swelling; black tongue. Rarely hepatitis (including altered liver function and jaundice). *Endocrine:* Testicular swelling and gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido; elevated or lowered blood sugar levels. *Other:* Dizziness, weakness; fatigue; headache; weight gain or loss; increased perspiration; urinary frequency; mydriasis; drowsiness; alopecia. *Withdrawal Symptoms:* Abrupt cessation after prolonged administration may produce nausea, headache, and malaise. These are not indicative of addiction.

OVERDOSAGE: All patients suspected of having taken an overdosage should be admitted to a hospital as soon as possible. Treatment is symptomatic and supportive. However, the intravenous administration of 1–3 mg of physostigmine salicylate is reported to reverse the symptoms of tricyclic antidepressant poisoning. Because physostigmine is rapidly metabolized, the dosage of physostigmine should be repeated as required particularly if life-threatening signs such as arrhythmias, convulsions, and deep coma recur or persist after the initial dosage of physostigmine. On this basis, in severe overdosage with perphenazine-amitriptyline combinations, symptomatic treatment of central anticholinergic effects with physostigmine salicylate should be considered.

MEDICAL DIRECTOR'S PAGE

Bruce H. Medd, M.D., Director of Professional Services

THE FAMILY PHYSICIAN AND THE PROBLEM DRINKER

Recognizing the alcoholic patient

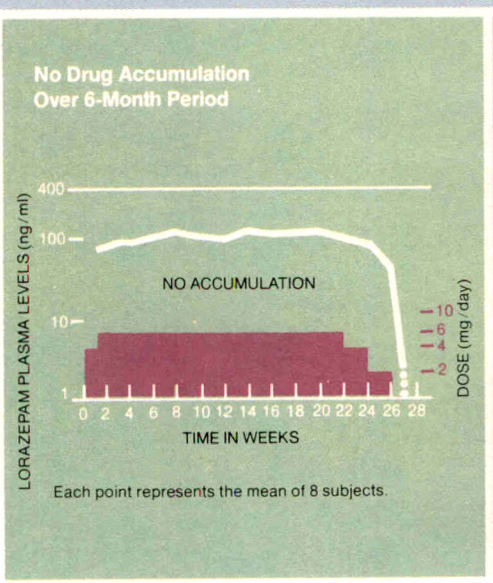
It is estimated that one out of every 20 patients seen by the family physician is suffering from the adverse physical and emotional effects of alcohol abuse.[1] However, data suggest that only 1 in 10 alcoholics is diagnosed and treated as such.[2] It is believed that the diagnosis is often missed because most patients rarely complain about or wish to discuss their alcoholism. Instead, they present complaints relating to excessive anxiety and tension, gastrointestinal disturbances, sleep problems and other general physical or psychological symptoms.[1]

The increased emphasis on the disease concept of alcoholism has encouraged the physician to improve diagnostic and treatment skills in this area. This can best be initiated with the recognition by all professionals that alcohol is a widely abused *psychoactive drug* of the sedative/depressant class and that it is highly *addictive,* exhibiting all four parameters of drug dependence as defined by the World Health Organization: *psychic* dependence, *physical* dependence, development of *tolerance* and characteristic *abstinence* (withdrawal) *syndrome*.[2]

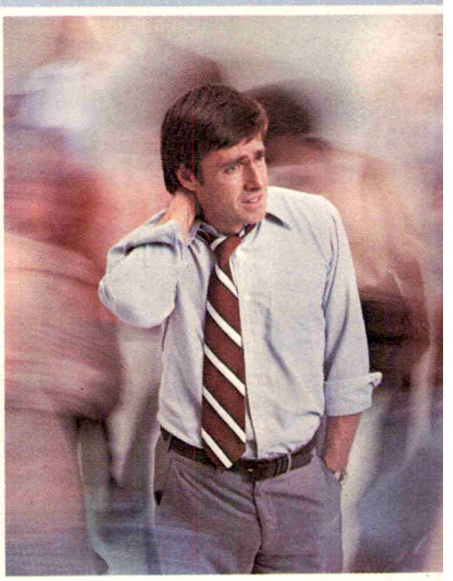
As alcoholism and alcohol-related disorders tend to follow the same pattern as other diseases—including onset, acute episodes, remission, relapse, deterioration and even death—the sooner diagnosis is made, the better the prognosis. Prompt identification is also important as alcoholics generally tend to misuse all medication in the same way that they abuse alcohol, often increasing dosages and refilling prescriptions given for the presenting complaints without their physician's knowledge.[3] It should also be noted that with continued drinking an enzyme system—the microsomal ethanol oxidizing system (MEOS)—is induced, which is associated with a nonspecific enhancement of a wide variety of microsomal enzymes. This results in an altered metabolism of many commonly prescribed medicines, *i.e.,* half-life may be markedly shortened in the absence of alcohol, whereas it may be prolonged when the same medication is taken in combination with alcohol.[4] Therefore, when use of any other psychoactive medication, *i.e.,* sedatives, hypnotics and minor tranquilizers, is deemed necessary in these dependency-prone individuals, close supervision should be maintained.

No one is in a better position to detect the patient with alcohol problems than the family physician, and there are many physical and psychological manifestations of alcoholism that can be detected long before the appearance of such classic signs as red face, bloodshot eyes, shaky hands, enlarged liver or frank malnutrition.[1] The accompanying table lists some of the more common *early* indications of alcohol abuse as presented by several authorities in the field.[1,2,5]

GUIDELINES FOR EARLY DETECTION OF ALCOHOLISM



Physical clues	
Gastrointestinal	vomiting (often before breakfast); nausea; dysphagia; diarrhea; vague abdominal complaints
Neurologic	blackouts; insomnia, headaches
Cardiovascular	palpitations; tachycardia
Traumatic	frequent accidents; falls or injuries of vague origin; cigarette burns on hands, chest
Psychological clues	
Behavioral	frequent financial difficulties; excessive absenteeism and poor performance at work; marital discord or multiple divorces; immoderate use of coffee, tea, tobacco, drugs
Emotional	anxiety; panic attacks; hallucinations; depression, suicidal ideation
Laboratory findings	hyperlipidemia; abnormal liver and/or kidney function; anemia; blood alcohol of 0.15% (almost pathognomonic for alcoholism)[1]



If you would like to receive a copy of a screening chart offering a wide range of clues to the early detection of alcoholism, ask your Roche representative or write to me: Bruce H. Medd, M.D., Director of Professional Services, Roche Laboratories, Division of Hoffmann-La Roche Inc., Nutley, New Jersey 07110.

How do you choose a minor tranquilizer?

Wyeth Laboratories
Philadelphia, PA 19101
TM

Pharmacokinetics

Ativan (lorazepam) is eliminated more rapidly than other benzodiazepines; generates no clinically active metabolites. The half-life of free lorazepam is about 12 hours; steady-state blood levels are attained in 2-3 days. (Comparable data for diazepam: 20-50 hours and at least 7-10 days.) Ativan shows no evidence of accumulation, even when given in high doses for as long as 6 months. (The pharmacokinetic profile of a drug can define such characteristics as absorption, distribution, metabolism and elimination but cannot, at present, be directly related to its therapeutic effectiveness.)

Anxiety neuroses

In many nationwide studies involving thousands of patients with anxiety neuroses, Ativan (lorazepam) consistently provided significant relief of anxiety, tension, agitation and irritability as measured by standard Hamilton, Global (physician rated) and 35-Item (patient self-rated) scales.

Copyright © 1979, Wyeth Laboratories Div. of AHPC, N.Y., N.Y. All rights reserved.

They're all about the same, aren't they? Until recently, that seemed to sum up the prevalent attitude about the benzodiazepines. After all, they all work similarly and all are effective anxiolytics. With seven of these compounds now available, however, differences have begun to emerge. Foremost among them: different metabolic pathways, which distinguish the relatively short-acting Ativan (lorazepam) from long-acting diazepam, clorazepate and chlordiazepoxide. At the same time, your choice can be made with confidence in the clinical record of Ativan, which confirms its value in anxiety neuroses and in significant anxiety associated with functional or organic disorders, as well as in older patients.

Consider the record of Ativan:

Anxiety in cardiovascular disorders

Ativan (lorazepam) has been specifically evaluated and found effective in seven common protocol, double-blind studies involving 423 patients (211 on Ativan) whose anxiety was related to organic and functional cardiovascular disorders. The cardiovascular component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in gastrointestinal disorders

So far, nine common protocol, double-blind studies of Ativan have focused on anxious patients with functional or organic gastrointestinal complaints (457 patients, 234 on Ativan). Ativan was clearly effective in reducing the anxiety of these patients. The gastrointestinal component has not, of course, been shown to be significantly benefited by such therapy.

Anxiety in the aging patient

Because its simple metabolism is not readily impaired with advancing age, and accumulation is not likely to present a problem, Ativan is a good choice for older patients. Those who have trouble swallowing solid medication appreciate the small Ativan tablet, which is tasteless and disintegrates within seconds in water or fruit juice.

Ativan® (lorazepam) for Anxiety

See important information on following page.

Brief Summary of Prescribing Information

Indications and Usage: Symptomatic relief of anxiety, tension, agitation, irritability and insomnia associated with anxiety neuroses and transient situational disturbances; anxiety associated with depressive symptoms and as a treatment of symptoms of anxiety if such symptoms are a significant feature of functional or organic disorders, particularly gastrointestinal or cardiovascular.

Effectiveness in long-term use, i.e., more than 4 months, has not been assessed by systematic clinical studies. Reassess periodically usefulness of the drug for the individual patient.

Contraindications: Known sensitivity to benzodiazepines or acute narrow-angle glaucoma.

Warnings: Not recommended in primary depressive disorders or psychoses. As with all CNS-acting drugs, warn patients on lorazepam not to operate machinery or motor vehicles, and of diminished tolerance for alcohol and other CNS depressants.

Physical and Psychological Dependence: Withdrawal symptoms like those noted with barbiturates and alcohol have occurred following abrupt discontinuance of benzodiazepines (including convulsions, tremor, abdominal and muscle cramps, vomiting and sweating). Addiction-prone individuals, e.g. drug addicts and alcoholics, should be under careful surveillance when on benzodiazepines because of their predisposition to habituation and dependence. Withdrawal symptoms have also been reported following abrupt discontinuance of benzodiazepines taken continuously at therapeutic levels for several months.

Precautions: In depression accompanying anxiety, consider possibility for suicide.

For elderly or debilitated patients, initial daily dosage should not exceed 2mg to avoid oversedation.

Terminate dosage gradually since abrupt withdrawal of any antianxiety agent may result in symptoms like those being treated: anxiety, agitation, irritability, tension, insomnia and occasional convulsions.

Observe usual precautions with impaired renal or hepatic function.

Where gastrointestinal or cardiovascular disorders coexist with anxiety, note that lorazepam has not been shown of significant benefit in treating gastrointestinal or cardiovascular component.

Esophageal dilation occurred in rats treated with lorazepam for more than 1 year at 6mg/kg/day. No effect dose was 1.25mg/kg/day (approximately 6 times the maximum human therapeutic dose of 10mg/day). Effect was reversible only when treatment was withdrawn within 2 months of first observation. Clinical significance is unknown; but use of lorazepam for prolonged periods and in geriatric patients requires caution and frequent monitoring for symptoms of upper G.I. disease.

Safety and effectiveness in children under 12 years have not been established.

ESSENTIAL LABORATORY TESTS: Some patients have developed leukopenia; some have had elevations of LDH. As with other benzodiazepines, periodic blood counts and liver function tests are recommended during long-term therapy.

CLINICALLY SIGNIFICANT DRUG INTERACTIONS: Benzodiazepines produce CNS depressant effects when administered with such medications as barbiturates or alcohol.

CARCINOGENESIS AND MUTAGENESIS: No evidence of carcinogenic potential emerged in rats during an 18-month study. No studies regarding mutagenesis have been performed.

PREGNANCY: Reproductive studies were performed in mice, rats, and 2 strains of rabbits. Occasional anomalies (reduction of tarsals, tibia, metatarsals, malrotated limbs, gastroschisis, malformed skull and microphthalmia) were seen in drug-treated rabbits without relationship to dosage. Although all these anomalies were not present in the concurrent control group, they have been reported to occur randomly in historical controls. At 40mg/kg and higher, there was evidence of fetal resorption and increased fetal loss in rabbits which was not seen at lower doses. Clinical significance of these findings is not known. However, increased risk of congenital malformations associated with use of minor tranquilizers (chlordiazepoxide, diazepam and meprobamate) during first trimester of pregnancy has been suggested in several studies. Because use of these drugs is rarely a matter of urgency, use of lorazepam during this period should almost always be avoided. Possibility that a woman of child-bearing potential may be pregnant at institution of therapy should be considered. Advise patients if they become pregnant to communicate with their physician about desirability of discontinuing the drug.

In humans, blood levels from umbilical cord blood indicate placental transfer of lorazepam and its glucuronide.

NURSING MOTHERS: It is not known if oral lorazepam is excreted in human milk like other benzodiazepines. As a general rule, nursing should not be undertaken while on a drug since many drugs are excreted in milk.

Adverse Reactions, if they occur, are usually observed at beginning of therapy and generally disappear on continued medication or on decreasing dose. In a sample of about 3,500 anxious patients, most frequent adverse reaction is sedation (15.9%), followed by dizziness (6.9%), weakness (4.2%) and unsteadiness (3.4%). Less frequent are disorientation, depression, nausea, change in appetite, headache, sleep disturbance, agitation, dermatological symptoms, eye function disturbance, various gastrointestinal symptoms and autonomic manifestations. Incidence of sedation and unsteadiness increased with age. Small decreases in blood pressure have been noted but are not clinically significant, probably being related to relief of anxiety.

Overdosage: In management of overdosage with any drug, bear in mind that multiple agents may have been taken. Manifestations of overdosage include somnolence, confusion and coma. Induce vomiting and/or undertake gastric lavage followed by general supportive care, monitoring of vital signs and close observation. Hypotension, though unlikely, usually may be controlled with Levarterenol Bitartrate Injection U.S.P. Usefulness of dialysis has not been determined.

Ativan® IV for (lorazepam) Anxiety

Dosage: **Individualize for maximum beneficial effects. Increase dose gradually when needed, giving higher evening dose before increasing daytime doses. Anxiety, usually 2-3mg/day given b.i.d. or t.i.d.; dosage may vary from 1 to 10mg/day in divided doses. For elderly or debilitated, initially 1-2mg/day; insomnia due to anxiety or transient situational stress, 2-4mg h.s.**

How Supplied: **0.5, 1.0 and 2.0mg tablets.**

SURMONTIL®
(TRIMIPRAMINE MALEATE)

As she sleeps... her antidepressant goes to work.

Promptly improves sleep patterns.
In a recent multicenter study among 89 depressed outpatients, a substantial majority had improved sleep patterns in the first week. Peak antidepressant effects occurred at 3 to 4 weeks.[1]

Relieves fatigue and anxiety.

Improved sleep generally lessens daytime fatigue. And the prompt anxiety-reducing effect of Surmontil[2] can help patients function better in the first weeks of therapy.

Low incidence of side effects.[3-5]

Effective in single nighttime dose after initial dosage titration.[2]

Before prescribing, please see complete product information, a summary of which follows:

CONTRAINDICATIONS: Contraindicated in cases of known hypersensitivity to the drug, and during the acute recovery period after myocardial infarction. The possibility of cross-sensitivity to other dibenzazepine compounds should be kept in mind. Surmontil should not be given in conjunction with drugs of the monoamine oxidase inhibitor (MAOI) class. At least two weeks should elapse between cessation of therapy with an MAOI and institution of therapy with Surmontil (trimipramine maleate).

WARNINGS: Children: This drug is not recommended for use in children, since safety and effectiveness in the pediatric age group have not been established. **Adults:** Use extreme caution in giving the drug to patients with evidence of cardiovascular disease. Caution is advised in patients with: increased intraocular pressure, history of urinary retention, narrow-angle glaucoma, seizure disorder, hyperthyroidism, a need for thyroid medication. In patients receiving guanethidine or similar agents, Surmontil may block the pharmacologic effects of these drugs. Warn patients that the drug may impair the mental or physical abilities required for driving or performing other potentially hazardous tasks.

PRECAUTIONS: Because of an inherently serious suicide potential, the nonhospitalized severely depressed patient should be given the smallest drug amount feasible. In schizophrenic patients, activation of the psychosis may occur and require reduction of dosage or the addition of a major tranquilizer to the medication schedule. Manic or hypomanic episodes may occur, especially in patients with cyclic-type disorders; Surmontil may have to be discontinued until the episode is relieved and reinstituted, if required, at lower dosage. Limit concurrent administration of Surmontil and electroconvulsive therapy to those patients for whom it is essential. When possible, discontinue the drug for several days prior to elective surgery. The use of alcoholic drinks during therapy may provoke exaggerated response. Potentiation of effects has been reported when tricyclic antidepressants were administered with sympathomimetic amines, local decongestants, local anesthetics containing epinephrine, atropine, or drugs with an anticholinergic effect. Drugs having a parasympathetic effect, including tricyclic antidepressants, may alter ejaculatory response.

Usage in pregnancy: Pregnancy Category C. Surmontil has shown evidence of embryotoxicity and/or increased incidence of major anomalies in rats or rabbits at doses 20 times the human dose. There are no adequate and well-controlled studies in pregnant women. Surmontil should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: When tricyclic antidepressants are used, each of the following adverse reactions must be considered, although some have not in fact been reported with Surmontil.

Cardiovascular—Hypotension, hypertension, tachycardia, palpitation, myocardial infarction, arrhythmias, heart block, stroke.

Psychiatric—Confusional states (especially in the elderly) with hallucinations, disorientation, delusions; anxiety, restlessness, agitation; insomnia and nightmares; hypomania; exacerbation of psychosis.

Neurologic—Numbness, tingling, paresthesias of extremities; incoordination, ataxia, tremors; peripheral neuropathy; extrapyramidal symptoms; seizures, alterations in EEG patterns; tinnitus.

Anticholinergic—Dry mouth and, rarely, associated sublingual adenitis; blurred vision, disturbances of accommodation, mydriasis, constipation, paralytic ileus; urinary retention, delayed micturition, dilation of the urinary tract.

Allergic—Skin rash, petechiae, urticaria, itching, photosensitization, edema of face and tongue.

Hematologic—Bone-marrow depression including agranulocytosis, eosinophilia; purpura; thrombocytopenia. Leukocyte and differential counts should be performed in any patient who develops fever and sore throat during therapy; the drug should be discontinued if there is evidence of pathologic neutrophil depression.

Gastrointestinal—Nausea and vomiting, anorexia, epigastric distress, diarrhea, peculiar taste, stomatitis, abdominal cramps, black tongue.

Endocrine—Gynecomastia in the male; breast enlargement and galactorrhea in the female; increased or decreased libido, impotence; testicular swelling; elevation or depression of blood-sugar levels.

Other—Jaundice (simulating obstructive); altered liver function; weight gain or loss; perspiration; flushing; urinary frequency; drowsiness, dizziness, weakness, and fatigue; headache; parotid swelling; alopecia.

Withdrawal Symptoms—Though not indicative of addiction, abrupt cessation of treatment after prolonged therapy may produce nausea, headache, and malaise.

SUPPLIED: 25 mg in bottles of 100 opaque blue and yellow capsules, 50 mg in bottles of 100 opaque blue and orange capsules.

GRID® APPROACHES TO MANAGING *New!* STRESS

By **Robert R. Blake** *and* **Jane Srygley Mouton,** *both of Scientific Methods, Inc., Austin, Texas.* This volume presents an innovative, unified approach to stress, stress-related illnesses and stress management. It employs the *Grid®*, a graphic tool for assessing and depicting the functional interplay of elements within a dynamic system and the variable impact of those elements on that system.

The text begins by reviewing the interrelationship of mental states and physical systems. The *Grid* itself is then brought into play. Using two axes, it graphically depicts an individual's concern for things or outcomes on the one hand and his concern for people on the other. Each axis is divided into nine segments so that coordinates can be used to define the person's *Grid* orientation: his attitude toward the world around him. Thus, a 9,1 orientation indicates a high concern for things and outcomes and a low concern for people; a 1,9 orientation shows a low concern for things and a high concern for people; and so on.

Individual chapters then detail the five basic *Grid* orientations or styles. These reveal the various combinations of concern for things and people. Each orientation is analyzed with respect to motivation, conflict, extremes of positivity and negativity within that orientation, focal stress, and implications for the individual's mental and physical health. Each orientation is shown to have different effects on the holistic health of the individual. A chapter also is included on double dominant theories, which deal with orientations composed of two conflicting or alternating *Grid* styles.

The information and theories presented to this point are then applied to concepts and practices of prevention and treatment. The former is discussed with respect to the role of will and intentionality in bringing about change, short-term prevention through risks associated with specific *Grid* styles, prevention through a positive attitude toward good everyday health practices, and long-term prevention through appropriate childrearing practices. Treatment receives equally thorough analysis in discussions of techniques such as relaxation, biofeedback, assertiveness training, desensitization, and flooding. *'80, 208 pp., 14 il., 1 table, $15.50*

New! **STRUCTURING CHILD BEHAVIOR THROUGH VISUAL ART: A Therapeutic, Individualized Art Program to Develop Positive Behavior Attitudes in Children** *by* **Florence Singer,** *School of the Art Institute of Chicago, Chicago.* In this book the author provides practical ideas for using art therapy to structure the behavior of emotionally maladjusted, behaviorally disturbed and learning disabled children. Following a review of history and theory, the physical environment, work process, student-instructor relationship, goals and objectives, and lesson plans are detailed. A chapter of case histories is included. The numerous appendices constitute an invaluable reference to testing centers, art therapy education institutions, research consultants, resource centers, and additional reading. *'80, 152 pp., 33 il., $15.75*

HYPNOSIS INDUCTION TECHNICS (5th Ptg.) *by* **Myron Teitelbaum.** *Foreword by* **Michael M. Gilbert.** *'80, 200 pp., $12.50*

New! **THE DEVELOPMENT OF THE BRAIN: Biological and Functional Perspectives** *by* **Stanislav Reinis** *and* **Jerome M. Goldman,** *both of Univ. of Waterloo, Waterloo, Ontario, Canada. '80, 416 pp., 192 il., 17 tables, $29.75*

New! **THE ENERGY COUPLE: The New Sexuality** *by* **Douglas Q. Corey** *and* **Jeannette P. Maas,** *both of Savusavu, Fiji.* A complete system of sexual practice, based on freedom and creativity, is herein delineated. This system stresses the enhancement of the physical dimension, but it also underscores a special kind of consciousness experience. *'80, 160 pp., 42 il., $9.95*

WOMEN WHO DRINK: Alcoholic Experience and Psychotherapy *edited by* **Vasanti Burtle,** *Los Angeles. Forewords by* **Phyllis K. Snyder, Jan DuPlain** *and* **George Staub.** *(14 Contributors) '79, 304 pp., 3 il., 9 tables, $21.00*

SENSORY ISOLATION AND PERSONALITY CHANGE *compiled and edited by* **Mark Kammerman,** *Labyrinth Corp., Beverly Hills, California. (13 Contributors)* Authorities in experimental psychology and psychiatry examine the status of sensory isolation and assess its potential as a tool for personality change. The effects of sensory deprivation in both bed confinement and water suspension isolation are documented, and the uses of sensory isolation as a method of exploring the unconscious mind are detailed. *'77, 324 pp., 2 il., 39 tables, $16.25*

HELPING THE MENTALLY RETARDED ACQUIRE PLAY SKILLS: A Behavioral Approach *by* **Paul Wehman,** *Virginia Commonwealth Univ., Richmond. Contribution by* **Marty Abramson.** *'77, 244 pp., 5 il., 26 tables, $16.00*

FORENSIC PSYCHIATRY: A Practical Guide for Lawyers and Psychiatrists *by* **Robert L. Sadoff,** *Univ. of Pennsylvania, Philadelphia.* With this practical text, the psychiatrist can become familiar with his specific functions within the law. The book is designed as a practical guide for lawyers and psychiatrists working together in areas of mental competency, criminal responsibility, domestic relations, commitment procedures, traumatic illnesses, drug and alcohol problems, sexual matters and juvenile crimes. Case citations and a psychiatric glossary are provided for the lawyer; outlines of interviews and forensic psychiatric reports are included for the psychiatrist. *'75, 272 pp., $18.50*

PARAPSYCHOLOGY: Frontier Science of the Mind (5th Ptg.) *by* **J. B. Rhine** *and* **J. G. Pratt,** *both of Duke Univ., Durham, North Carolina. '74, 236 pp., 10 il., 10 tables, $8.75*

A PRACTICAL HANDBOOK OF PSYCHIATRY *edited by* **Joseph R. Novello,** *Univ. of Michigan, Ann Arbor. (17 Contributors) '74, 648 pp., 10 il., 47 tables, $21.50*

PSYCHIATRIC ASSESSMENT BY SPEECH AND HEARING BEHAVIOR *by* **Clyde L. Rousey,** *The Menninger Foundation, Topeka, Kansas. Foreword by* **J. Cotter Hirschberg.** *(18 Contributors) '74, 392 pp., 12 tables, $24.00*

New! **A PRACTICAL GUIDE FOR HANDLING DRUG CRISES** *by* **Jonathan W. Lehrman, Lawrence L. Ruhf** *and* **E. T. Mellor.** Straightforward and accurate data on drugs and drug crisis management are presented in this text. Separate chapters cover crises involving amphetamines, anticholinergics, aspirin, cannabis, cocaine, hallucinogens, narcotics, phencyclidine, sedative-hypnotics, and solvents and aerosols. For each, the authors provide description; history; effects; medical, nonmedical and illicit uses; physical and psychological dependence; and myths and realities. *'80, 80 pp., cloth-$12.75, paper-$7.50*

New! **THE OLDER WOMAN: Lavender Rose or Gray Panther** *edited by* **Marie Marschall Fuller,** *Texas Woman's Univ., and* **Cora Ann Martin,** *North Texas State Univ., both of Denton. (41 Contributors) '80, 368 pp., 19 tables, $16.75, paper*

New! **SOCIAL PSYCHOLOGICAL PERSPECTIVES ON LEISURE AND RECREATION** *edited by* **Seppo E. Iso-Ahola,** *Univ. of Iowa, Iowa City. (18 Contributors) '80, 448 pp., 6 il., 10 tables, $19.75*

FIFTY YEARS IN PSYCHIATRY: A Living History *by* **Roy R. Grinker, Sr.,** *Michael Reese Hospital and Medical Center, Chicago.* The author herein presents a highly readable overview of the last five decades in the field of psychiatry. Chapters are included on general systems and unified theories; stress and anxiety; depressions; borderline states; therapies, service, and the peer groups; and research. Personal glimpses into the author's life as a student, analysand, and beginning psychiatrist are also provided along with a look at the profession's future. *'79, 280 pp., 1 table, $15.50*

NEUROCHEMISTRY OF AMINOSUGARS: Neurochemistry and Neuropathology of the Complex Carbohydrates *by* **Eric G. Brunngraber,** *Univ. of Missouri, Columbia.* This reference reviews the biochemistry of the gangliosides, glycosaminoglycans, and glycoproteins of brain tissues, with emphasis on associated heteropolysaccharide structures. The author examines the functional significance of these structures and describes neuropathological conditions caused by anomalies in complex carbohydrate metabolism. The text is augmented by a review of the literature that lists over 7000 references. *'79, 720 pp., 9 il., 7 tables, $34.75*

DRUGS AND THE ELDERLY: Social and Pharmacological Issues *edited by* **David M. Petersen, Frank J. Whittington** *and* **Barbara P. Payne,** *all of Georgia State Univ., Atlanta. Foreword by* **Peter G. Bourne.** *(18 Contributors)* Drug use and misuse among the elderly are carefully examined in this text. Articles are included on drug side effects, drug interactions, self-medication, and the practice of community and institutional pharmacy. Other discussions emphasize the medical community's responsibility for educating the elderly and suggest strategies for drug education. *'79, 280 pp., 5 il., 9 tables, $26.25*

THE DIAGNOSIS AND TREATMENT OF ALCOHOLISM (2nd Ed.) *by* **Gary G. Forrest,** *Psychotherapy Associates, Colorado Springs, Colorado. '78, 364 pp., 7 tables, cloth-$19.25, paper-$14.25*

HUMAN BEHAVIOR AND BRAIN FUNCTION *edited by* **Harvey J. Widroe,** *Walnut Creek Psychiatric Hospital, Walnut Creek, California. (8 Contributors)* Psychophysiological research studies pertinent to the understanding and treatment of minimal cerebral dysfunction in children and adolescents, aggression control defects, schizophrenia, manic depressive psychosis, heroin addiction, alcohol addiction, and behavior disorders secondary to cerebral arteriosclerosis are presented. *'75, 132 pp., 10 il., 6 tables, $9.25*

CHILDREN'S EXPERIENCE WITH DEATH *by* **Rose Zeligs,** *Private Practice, Sherman Oaks, California.* This clearly written book deals with every aspect of death as it touches the lives of children. A review in ***American Journal of Psychiatry*** stated, "This book is well written, lucidly presented, and adequately documented. . . ." According to a review in ***Modern Medicine,*** "This book merits a place in the library of every professional person who has to help a child in his experience of death." *'74, 264 pp., $13.75*

New!

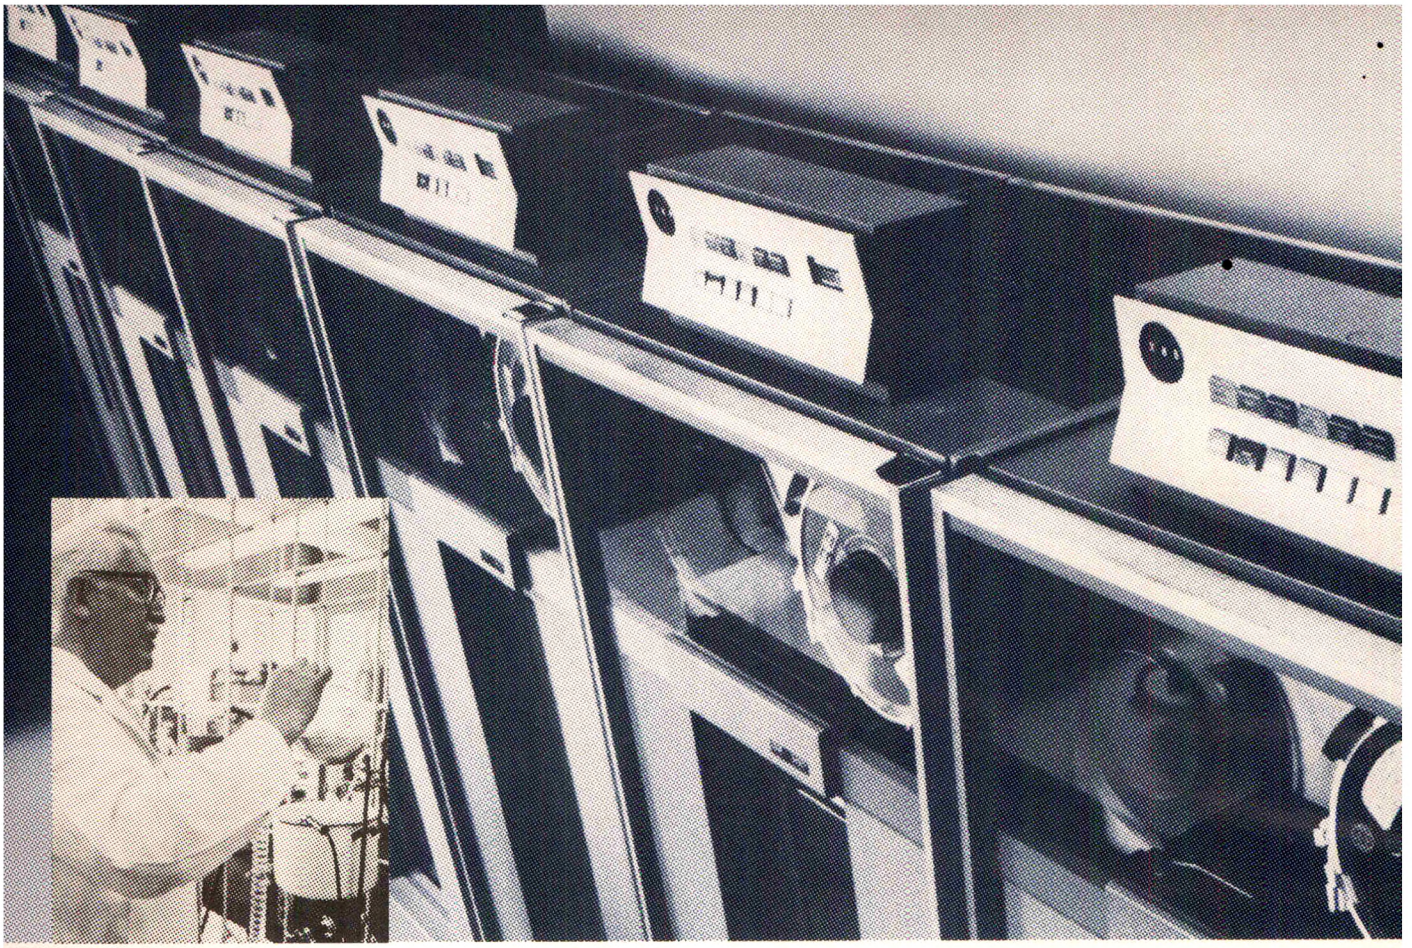
THE ADMINISTRATION OF MENTAL HEALTH SERVICES

Second Edition

Edited by **Saul Feldman,** *National Institute of Mental Health, Rockville, Maryland. (18 Contributors)* The Second Edition of this highly regarded book continues to offer comprehensive, well-documented information on the theory and practice of administration in mental health. The text comprises original contributions by a number of respected authorities who write in their own areas of expertise and experience.

The text begins with a general appraisal of contemporary mental health administration which reviews the progress made within such areas of the field as government recognition, training programs, and professional attitudes. This introduction provides a backdrop for the more specific analyses that follow.

The book includes chapters on:



- planning
- personnel management
- financial management
- budgeting and behavior
- management information
- organizational sociology
- interorganizational relations
- the governmental system
- community participation
- mental health law
- decision-making and the process of change
- program evaluation

The chapters on mental health law and financial management are completely new, while the others have been revamped wherever necessary to keep pace with the growing and changing profession. Each chapter is thoroughly referenced. In addition, a general bibliography of mental health administration follows the text. Detailed subject and author indexes are included.

A review of the First Edition appearing in ***Hospital and Community Psychiatry*** stated, "... the volume as a whole achieves clarity without sacrificing scholarship. As the best general introduction to mental health administration that has appeared to date, it should be a required text in every training program in mental health administration. . . ." *'80, 544 pp., 20 il., 24 tables, $49.75*

proven antianxiety

Highly specific calming action virtually free of unwanted side effects: this was the remarkable clinical promise of Librium (chlordiazepoxide HCl). And today this promise continues to be fulfilled in a wide variety of patients you see every day.

ROCHE

The published record on Librium is enormous. So large, in fact, it had to be put into a computer data bank and retrieval system. It's a record that shows Librium is highly effective in relieving anxiety; that Librium is seldom associated with serious side effects; that Librium rarely interferes with mental acuity at proper doses; that Librium is used concomitantly with primary medications. However, as with all CNS agents, patients should be warned against hazardous activities requiring complete alertness, and about possible combined effects with alcohol.

performance

Librium® (IV)
chlordiazepoxide HCl/Roche

5mg, 10mg, 25mg capsules

synonymous with relief of anxiety

- ☐ An unsurpassed safety record
- ☐ Minimal effect on mental acuity, in proper dosage
- ☐ Predictable patient response
- ☐ Is used concomitantly with primary medications, such as anticholinergics and cardiovascular drugs

Please see next page for summary of product information.

Librium® *5mg,10mg,25mg capsules*
chlordiazepoxide HCl/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Relief of anxiety and tension occurring alone or accompanying various disease states. Efficacy beyond four months not established by systematic clinical studies. Periodic reassessment of therapy recommended.

Contraindications: Patients with known hypersensitivity to the drug.

Warnings: Warn patients that mental and/or physical abilities required for tasks such as driving or operating machinery may be impaired, as may be mental alertness in children, and that concomitant use with alcohol or CNS depressants may have an additive effect. Though physical and psychological dependence have rarely been reported on recommended doses, use caution in administering to addiction-prone individuals or those who might increase dosage; withdrawal symptoms (including convulsions), following discontinuation of the drug and similar to those seen with barbiturates, have been reported.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: In the elderly and debilitated, and in children over six, limit to smallest effective dosage (initially 10 mg or less per day) to preclude ataxia or oversedation, increasing gradually as needed and tolerated. Not recommended in children under six. Though generally not recommended, if combination therapy with other psychotropics seems indicated, carefully consider individual pharmacologic effects, particularly in use of potentiating drugs such as MAO inhibitors and phenothiazines. Observe usual precautions in presence of impaired renal or hepatic function. Paradoxical reactions (*e.g.*, excitement, stimulation and acute rage) have been reported in psychiatric patients and hyperactive aggressive children. Employ usual precautions in treatment of anxiety states with evidence of impending depression; suicidal tendencies may be present and protective measures necessary. Variable effects on blood coagulation have been reported very rarely in patients receiving the drug and oral anticoagulants; causal relationship has not been established clinically.

Adverse Reactions: Drowsiness, ataxia and confusion may occur, especially in the elderly and debilitated. These are reversible in most instances by proper dosage adjustment, but are also occasionally observed at the lower dosage ranges. In a few instances syncope has been reported. Also encountered are isolated instances of skin eruptions, edema, minor menstrual irregularities, nausea and constipation, extrapyramidal symptoms, increased and decreased libido—all infrequent and generally controlled with dosage reduction; changes in EEG patterns (low-voltage fast activity) may appear during and after treatment; blood dyscrasias (including agranulocytosis), jaundice and hepatic dysfunction have been reported occasionally, making periodic blood counts and liver function tests advisable during protracted therapy.

Usual Daily Dosage: Individualize for maximum beneficial effects. *Oral–Adults:* Mild and moderate anxiety and tension, 5 or 10 mg *t.i.d.* or *q.i.d.*; severe states, 20 or 25 mg *t.i.d.* or *q.i.d. Geriatric patients:* 5 mg *b.i.d.* to *q.i.d.* (See Precautions.)

Supplied: Librium® (chlordiazepoxide HCl) *Capsules*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500; Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10; Prescription Paks of 50, available singly and in trays of 10. Libritabs® (chlordiazepoxide) *Tablets*, 5 mg, 10 mg and 25 mg—bottles of 100 and 500. With respect to clinical activity, capsules and tablets are indistinguishable.

He has five years to fight for your life

He is an American Heart Association Established Investigator, funded for five years to work on some phase of cardiovascular disease. He and his associates are researching ways to recognize a heart attack before severe damage occurs.

His ultimate goal is to decrease the present toll from cardiovascular diseases. Of the four Americans that die every minute this year from all causes, two will die from these diseases.

He is one of over 1,400 scientists supported by the American Heart Association who are fighting for your life.

But we need more money for more research that may produce earlier detection and better methods of treatment and prevention of cardiovascular diseases.

When a Heart Association volunteer asks for your money, think of the 1,400 scientific investigators. Help them fight for your life.

THE CHRONIC MENTAL PATIENT

Report of a Conference held in January 1978

Edited by

John A. Talbott, M.D.

with contributions by James T. Barter, M.D., Paul R. Friedman, J.D., Raymond Glasscote, M.A., Trevor D. Glenn, M.D., Norman V. Lourie, M.S.W., W. Walter Menninger, M.D., Arthur T. Meyerson, M.D., Kenneth Minkoff, M.D., Samuel Muszynski, M.S.W., Lucy D. Ozarin, M.D., Gordon L. Paul, Ph.D., Ronald Peterson, Steven S. Sharfstein, M.D., Judith Clark Turner, Jane Bloom Yohalem, J.D.

This 277-page Report of the Conference, sponsored by APA and President Carter's Commission on Mental Health, identifies the chronic mental patient population, spells out where they are and what their needs and rights are. It specifies what programs work and what programs do not work in meeting the needs of these patients. It elaborates on the obstacles to implementing effective programs and the economic issues involved. It delineates the pros and cons of case management and specifies responsibility for coordinating, implementing, and monitoring services to chronic mental patients.

Finally, it proposes a *Call to Action* which opens with this statement: "There is no more urgent concern than the needs of the chronic mentally ill who suffer from severe, persistent, or recurrent mental illnesses with residual social and vocational disabilities. As a result of the deinstitutionalization programs of the past decade and the continuing growth of high risk populations that generate chronically ill, the problems associated with the care of these patients constitute a national crisis."

Since the Conference, the APA Assembly and the Board of Trustees have both approved the "Call to Action" which calls upon the APA to take the lead in undertaking programs to elevate the prestige and value of work with chronic mentally ill patients.

It follows that all APA members should be thoroughly versed in the current problems of this chronic patient population. This is best accomplished by reading this Conference Report now available from APA Publications Services at $11.00 a copy.

Order Your Copy of the 1980 Membership Directory Now!

The latest listing of APA members (as of January 31, 1980) has just been published. Unlike previous editions, the 1980 Membership Directory, largely at the urging of President Dr. Donald G. Langsley, contains telephone numbers as well as names, addresses, membership class and membership status. A new format provides easy access to the alphabetical and geographical listings.

Another new addition to this Directory is a section containing the names and addresses of District Branch Executive Secretaries. Also included in this Directory is a list of Officers, the Board of Trustees and the Assembly, as well as past APA meetings, past Officers, Honorary and Distinguished Fellows and a membership table. This publication will provide readers with information about the APA and the most comprehensive listing of the membership since the 1977 Biographical Directory.

April 1980. Approximately 300 pages. Order #151. $13.00.

Before prescribing or administering, see Sandoz literature for full product information. The following is a brief summary.

Contraindications: Severe central nervous system depression, comatose states from any cause, hypertensive or hypotensive heart disease of extreme degree.

Warnings: Administer cautiously to patients who have previously exhibited a hypersensitivity reaction (e.g., blood dyscrasias, jaundice) to phenothiazines. Phenothiazines are capable of potentiating central nervous system depressants (e.g., anesthetics, opiates, alcohol, etc.) as well as atropine and phosphorus insecticides; carefully consider benefit versus risk in less severe disorders. During pregnancy, administer only when the potential benefits exceed the possible risks to mother and fetus.

Precautions: There have been infrequent reports of leukopenia and/or agranulocytosis and convulsive seizures. In epileptic patients, anticonvulsant medication should also be maintained. Pigmentary retinopathy, observed primarily in patients receiving larger than recommended doses, is characterized by diminution of visual acuity, brownish coloring of vision, and impairment of night vision; the possibility of its occurrence may be reduced by remaining within recommended dosage limits. Administer cautiously to patients participating in activities requiring complete mental alertness (e.g., driving), and increase dosage gradually. Orthostatic hypotension is more common in females than in males. Do not use epinephrine in treating drug-induced hypotension since phenothiazines may induce a reversed epinephrine effect on occasion. Daily doses in excess of 300 mg should be used only in severe neuropsychiatric conditions.

Adverse Reactions: *Central Nervous System*—Drowsiness, especially with large doses, early in treatment; infrequently, pseudoparkinsonism and other extrapyramidal symptoms; rarely, nocturnal confusion, hyperactivity, lethargy, psychotic reactions, restlessness, and headache. *Autonomic Nervous System*—Dryness of mouth, blurred vision, constipation, nausea, vomiting, diarrhea, nasal stuffiness, and pallor. *Endocrine System*—Galactorrhea, breast engorgement, amenorrhea, inhibition of ejaculation, and peripheral edema. *Skin*—Dermatitis and skin eruptions of the urticarial type, photosensitivity. *Cardiovascular System*—ECG changes (see *Cardiovascular Effects* below). *Other*—Rare cases described as parotid swelling.

It should be noted that efficacy, indications and untoward effects have varied with the different phenothiazines. It has been reported that old age lowers the tolerance for phenothiazines; the most common neurologic side effects are parkinsonism and akathisia, and the risk of agranulocytosis and leukopenia increases. The following reactions have occurred with phenothiazines and should be considered whenever one of these drugs is used. *Autonomic Reactions*—Miosis, obstipation, anorexia, paralytic ileus. *Cutaneous Reactions*—Erythema, exfoliative dermatitis, contact dermatitis. *Blood Dyscrasias*—Agranulocytosis, leukopenia, eosinophilia, thrombocytopenia, anemia, aplastic anemia, pancytopenia. *Allergic Reactions*—Fever, laryngeal edema, angioneurotic edema, asthma. *Hepatotoxicity*—Jaundice, biliary stasis. *Cardiovascular Effects*—Changes in terminal portion of electrocardiogram, including prolongation of Q-T interval, lowering and inversion of T-wave, and appearance of a wave tentatively identified as a bifid T or a U wave have been observed with phenothiazines, including Mellaril (thioridazine); these appear to be reversible and due to altered repolarization, not myocardial damage. While there is no evidence of a causal relationship between these changes and significant disturbance of cardiac rhythm, several sudden and unexpected deaths apparently due to cardiac arrest have occurred in patients showing characteristic electrocardiographic changes while taking the drug. While proposed, periodic electrocardiograms are not regarded as predictive. Hypotension, rarely resulting in cardiac arrest. *Extrapyramidal Symptoms*—Akathisia, agitation, motor restlessness, dystonic reactions, trismus, torticollis, opisthotonus, oculogyric crises, tremor, muscular rigidity, and akinesia. *Persistent Tardive Dyskinesia*—Persistent and sometimes irreversible tardive dyskinesia, characterized by rhythmical involuntary movements of the tongue, face, mouth, or jaw (e.g., protrusion of tongue, puffing of cheeks, puckering of mouth, chewing movements) and sometimes of extremities may occur on long-term therapy or after discontinuation of therapy, the risk being greater in elderly patients on high-dose therapy, especially females; if symptoms appear, discontinue all antipsychotic agents. Syndrome may be masked if treatment is reinstituted, dosage is increased, or antipsychotic agent is switched. Fine vermicular movements of tongue may be an early sign, and syndrome may not develop if medication is stopped at that time. *Endocrine Disturbances*—Menstrual irregularities, altered libido, gynecomastia, lactation, weight gain, edema, false positive pregnancy tests. *Urinary Disturbances*—Retention, incontinence. *Others*—Hyperpyrexia; behavioral effects suggestive of a paradoxical reaction, including excitement, bizarre dreams, aggravation of psychoses, and toxic confusional states; following long-term treatment, a peculiar skin-eye syndrome marked by progressive pigmentation of skin or conjunctiva and/or accompanied by discoloration of exposed sclera and cornea; stellate or irregular opacities of anterior lens and cornea; systemic lupus erythematosus-like syndrome.

Dosage: Dosage must be individualized according to the degree of mental and emotional disturbance, and the smallest effective dosage should be determined for each patient.

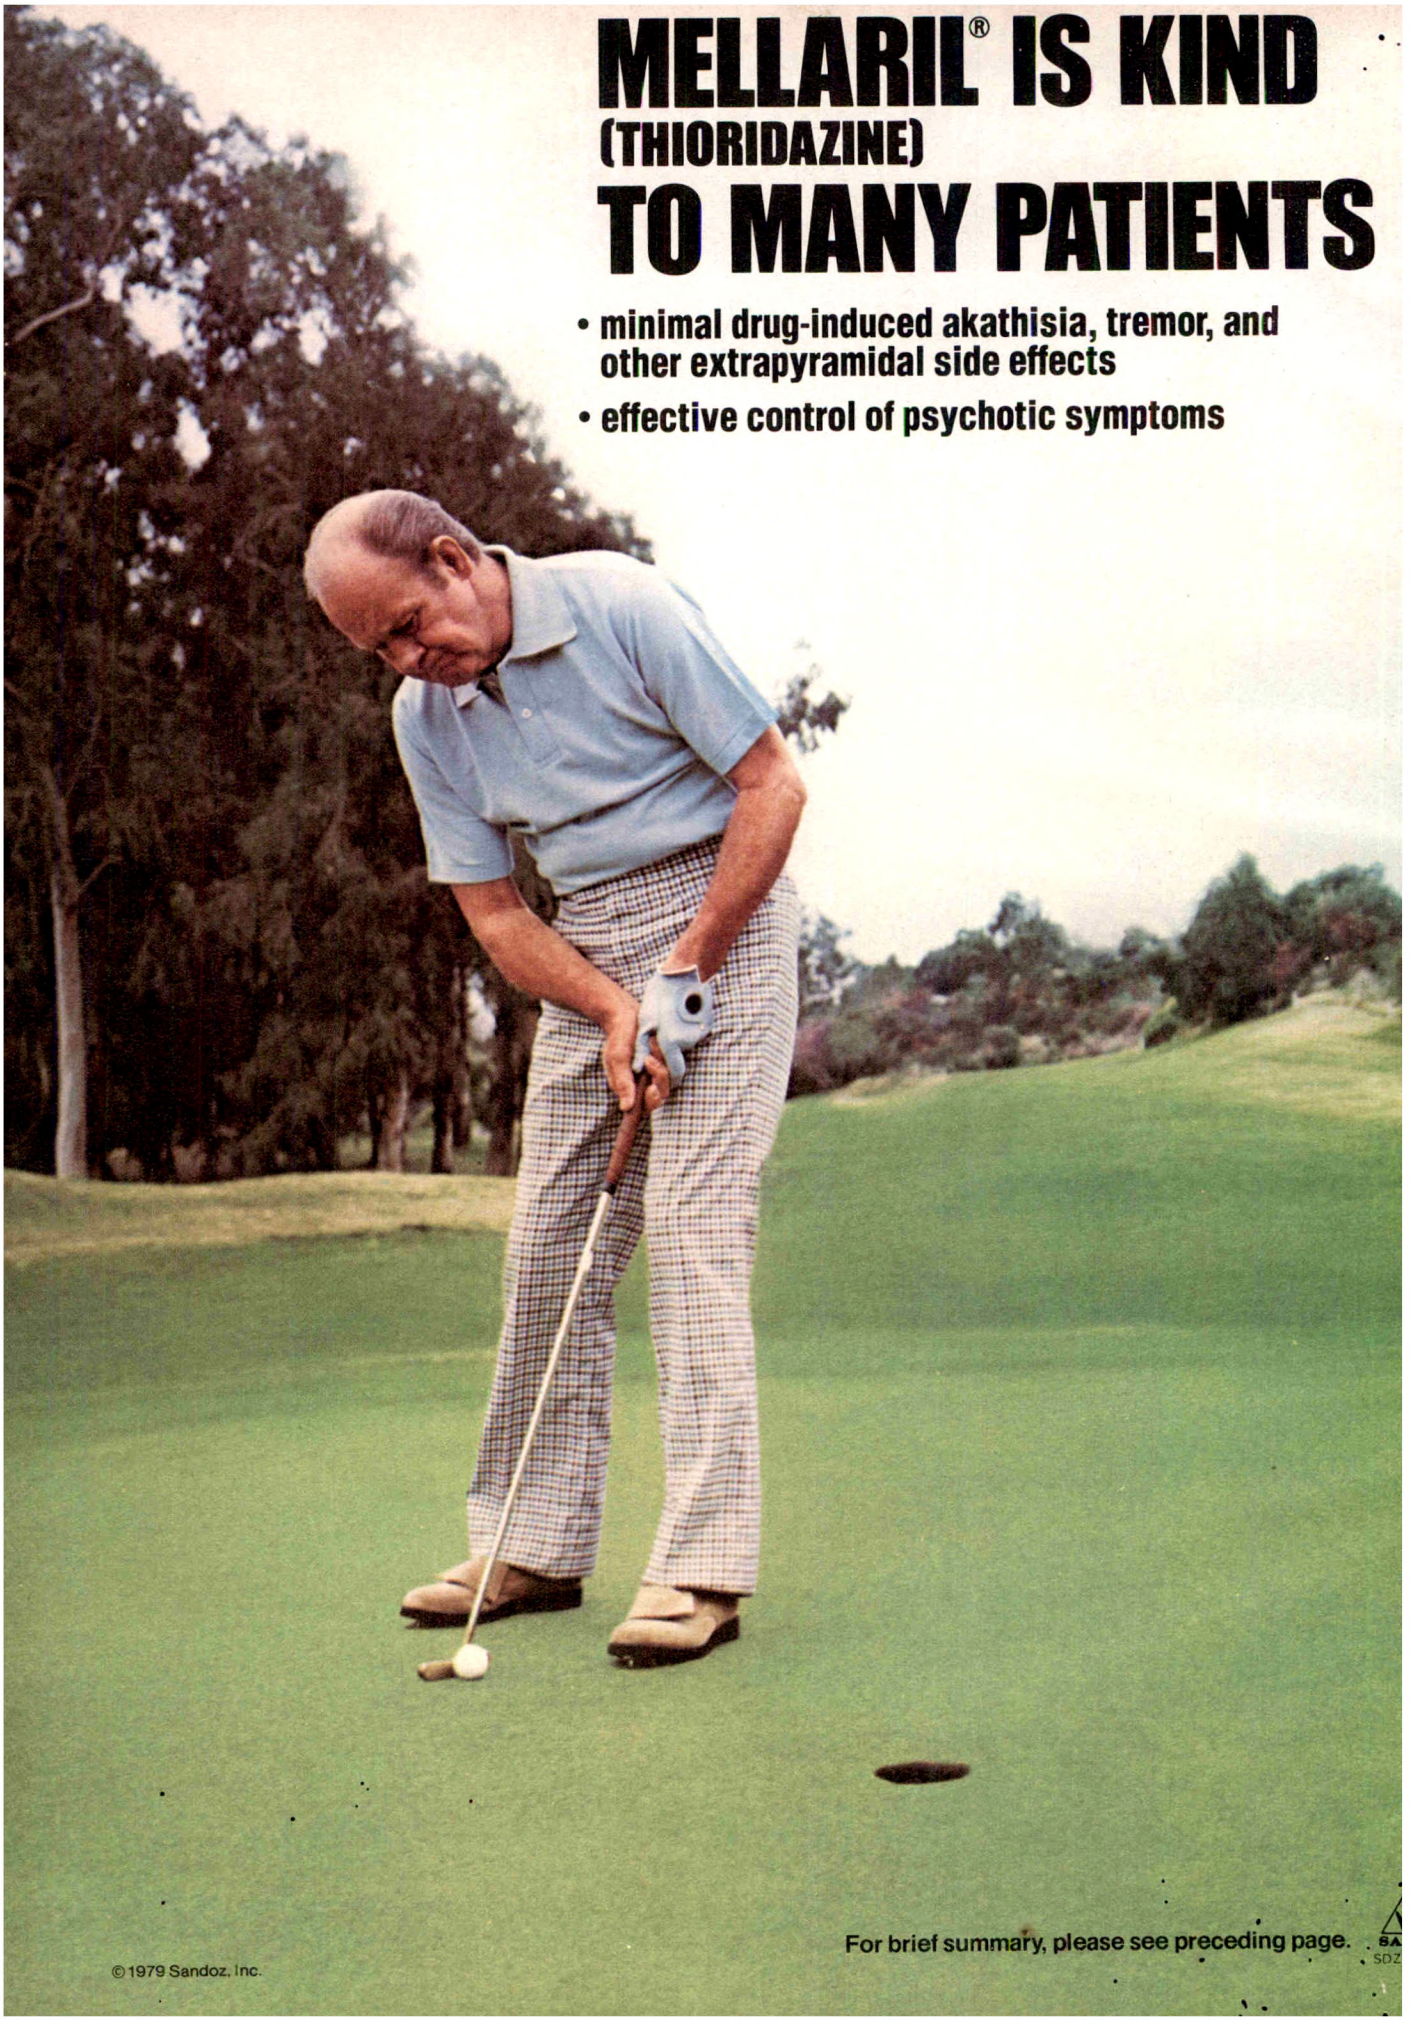
MELLARIL® IS KIND (THIORIDAZINE) TO MANY PATIENTS

- **minimal drug-induced akathisia, tremor, and other extrapyramidal side effects**
- **effective control of psychotic symptoms**



Mellaril® (thioridazine) is kind *two* ways to the patient with psychotic symptoms. It has an impressive record of relieving agitation, excitement, and hallucinations, while successfully helping the patient live and perform in the community. And, unlike other major tranquilizers, Mellaril (thioridazine) causes minimal akathisia or other extrapyramidal symptoms. Mellaril (thioridazine) is contraindicated in patients with hypertensive or hypotensive heart disease of extreme degree.

Effectiveness plus infrequent side effects—that's the kind of kindness the physician likes to see in a major tranquilizer!

MELLARIL® (THIORIDAZINE)

TABLETS: 50 mg, 100 mg, 150 mg, and 200 mg thioridazine HCl, USP

MELLARIL-S™ (thioridazine) SUSPENSION, per 5 ml (teaspoon): thioridazine base equivalent to 100 mg thioridazine HCl, USP

MELLARIL® IS KIND (THIORIDAZINE) TO MANY PATIENTS

- minimal drug-induced akathisia, tremor, and other extrapyramidal side effects
- effective control of psychotic symptoms

For brief summary, please see preceding page.

THE AMERICAN JOURNAL OF PSYCHIATRY

Psychophysiologic Factors in Sudden Cardiac Death

BY BERNARD LOWN, M.D., REGIS A. DESILVA, M.D., PETER REICH, M.D., AND BENJAMIN J. MURAWSKI, PH.D.

Sudden cardiac death due to ventricular fibrillation is the leading cause of fatality in the industrially developed world. A considerable body of evidence indicates that the higher nervous system modifies electrical activity of the heart and may trigger sudden death. The evidence for increased risk for ventricular fibrillation due to psychophysiologic factors is supported predominantly by animal studies, but increasing evidence is forthcoming from human studies. The involvement of psychiatrists, psychologists, and cardiologists in a multidisciplinary approach to managing patients at risk for sudden death from ventricular fibrillation is yielding significant insights and prolonging their lives.

Recognition of an association between sudden death and profound emotion dates to the very dawn of recorded history. Comprehension of such a relation is embedded in the matrix of common speech and documented in the most ancient of scripts, scrolls, and papyri. Yet until quite recently medical scientific inquiry stood aloof from the entire subject of sudden death, let alone examine the possible role of psychologic factors in its pathophysiology. This neglect was not by virtue of incomprehension of the magnitude of the problem. Rather it stemmed from the more general malaise to be found in any scientific field when methodologic tools have not yet been developed to probe adequately a given field of inquiry. Sudden death had been rationalized as the irreversible culmination of advanced coronary atherosclerosis, and since it occurred unpredictably in the community, it was seemingly outside the sphere of the physician's responsibility. However, the advent of direct-current defibrillation, cardioversion, coronary care units, heart rhythm monitoring devices, and, especially, cardiopulmonary resuscitation emphasized the reversible nature of sudden death due to ventricular fibrillation.

The initial questions posed regarding identification of the patient at increased risk for sudden death suggested that neural factors were implicated. In 1970, Lown and Ruberman (1) postulated that certain types of ventricular premature beats are harbingers of fatality. These extrasystoles are sporadic and often emerge without apparent physiologic basis. The cardiologist necessarily considers a hemodynamic explanation, wherein the ectopic beat is deemed to be an expression of enhanced myocardial ischemia. However, young and healthy subjects without demonstrable heart disease are by no means spared such rhythmic irregularities (2). A hemodynamic explanation, furthermore, does not account for the fact that there is a greater prevalence and severity of arrhythmia during a 24-hour electrocardiographic monitoring period, when the patient is largely passive, than during maximal exercise stress testing (3). Exercise testing induces peak heart rates and rises in blood pressure far in excess of the levels observed during passive monitoring. What then are the provocative factors for arrhythmia that are even more potent than a vigorous hemodynamic stress? It has been our working hypothesis that higher nervous activity triggered by psychologic factors can significantly affect cardiac electrophysiologic properties and may result both in ventricular premature beats and in lowering the threshold for ventricular fibrilla-

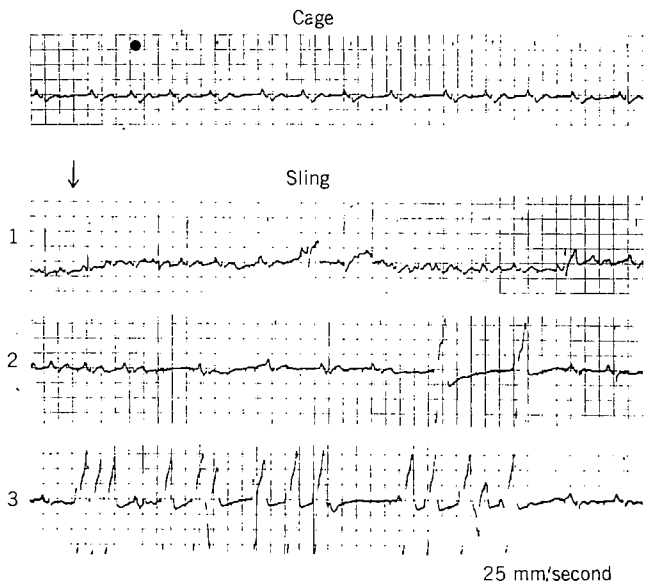
tion, the underlying basis for sudden cardiac death (4, 5).

Whenever patients dying suddenly have been electrocardiographically monitored at the time of death, the mechanism almost invariably has been ventricular fibrillation. This rhythm disorder is characterized by a chaotic disorganization of the heart beat, veritably an electrical storm of tumultuous and ineffectual colliding and dispersing wavelets of depolarization that annul synchronized activation of the contractile process. The result is abrupt cessation of cardiac pumping action, with irreversible brain damage ensuing within several minutes. It has long been entertained that this catastrophic arrhythmia leading to arrest of cardiac activity is precipitated by coronary thrombosis, myocardial infarction, or both. Yet in a majority of those who die suddenly fresh morphologic lesions, either in vessels or in heart muscle, are remarkable for their absence. Furthermore, patients who have been resuscitated from sudden cardiac death generally do not immediately reexperience ventricular fibrillation, although recurrence may occur at a later time. Thus, ventricular fibrillation may be deemed to be due to a sudden but momentary disruption of the electrical function of the heart. Sudden cardiac death may therefore be viewed as a reversible electrical accident. Lown and coworkers (6, 7) have postulated that transient risk factors momentarily destabilize the heart already afflicted with ischemic disease and thereby predispose it to self-regenerating repetitive electrical activity resulting in ventricular fibrillation. Among the major sources of transient risk factors is the central nervous system.

The validity of this hypothesis is of profound contemporary medical significance. Sudden cardiac death is the leading cause of fatality in the industrially developed world. It claims more lives than cancer, and about 1,200 individuals are stricken daily in the United States alone. The victims are predominantly male and frequently at the prime of life. Studies in animals as well as clinical observations sanction the view that neural and psychologic inputs to the heart may indeed trigger ventricular fibrillation. These findings deserve careful examination.

ANIMAL MODELS

In studying the role of psychologic stresses on predisposition of the heart to ventricular fibrillation, the arrhythmia of sudden death, a number of methodologic problems had to be overcome. Until recently no experimental data were available relating to the effect of psychologic variables on cardiac susceptibility to ventricular fibrillation. This was largely due to the absence of suitable methods for repeatedly determining cardiac vulnerability in the intact unanesthetized animal. Such assessment required the use of painful stimuli, induction of ventricular fibrillation, and use of traumatic resuscitation procedures that preclude meaningful investigation of psychologic variables. It was necessary to devise an appropriate electrical end-point that could serve as an index of vulnerability.



The physiologist measures cardiac vulnerability by applying increasing intensities of electrical pulses during the 20-millisecond interval of the cardiac cycle (referred to as the ventricular vulnerable period), coinciding with the apex of the T-wave of the surface electrocardiogram. The minimum current discharged during the vulnerable period that induces ventricular fibrillation is designated the ventricular fibrillation threshold. This index serves as a measure of electrical instability of the heart and its predisposition to malignant arrhythmias. A high threshold indicates a low vulnerability to fibrillation and vice versa. To obviate the psychologic and physical trauma attending precipitation of ventricular fibrillation and subsequent defibrillation, we have developed another marker for electrical stability of the myocardium, known as the repetitive extrasystole threshold (8–11). This method consists of delivering a graded electrical impulse to the heart early in diastole and coincident with the vulnerable period. Normally, one impulse evokes but a single ventricular response. As the current strength is progressively increased and approaches the ventricular fibrillation threshold, one stimulus will evoke two or more successive extrasystoles. The minimum current required to evoke two ventricular responses is designated the repetitive extrasystole threshold (8). This threshold is consistently 65% of the lowest current required to evoke ventricular fibrillation. The repetitive extrasystole threshold reliably tracks electrical current requirements for ventricular fibrillation, without awareness on the part of the animal (11).

Psychologic Stress and Ventricular Vulnerability

Using the repetitive extrasystole method, we have shown in dogs that psychologic stress profoundly affects vulnerability to ventricular arrhythmias and fibrillation (9–14). One group of dogs was left undisturbed in a cage, and in another cage dogs were immobilized in a Pavlovian sling and subjected to mild electric shocks. No shocks were administered after the first 3 days. The dogs that had been conditioned in these two environments were studied during recovery from acute myocardial infarction. During the period of recovery, at a time when heart rhythm was normal, return of an animal to the stressful sling environment provoked ventricular tachycardia (see figure 1). Acute coronary artery occlusion in the stressful environment resulted in an incidence of ventricular fibrillation that was three times higher than that in the nonstressful environment (14). Placing the animal in the stressful environment also resulted in elevations in blood levels of norepinephrine and total catecholamines.

Using the same cage and sling model, we also in-

FIGURE 1
Ventricular Arrhythmia Provoked by Psychologic Stress in a Dog with Previous Coronary Artery Occlusion[a]

[a]Several weeks earlier the dog had been placed in a Pavlovian sling and subjected to mild electrical shocks. The electrocardiogram indicates no arrhythmia when the dog was left undisturbed in the cage and, 1) immediately after transfer to the sling (arrow), acceleration in heart rate and unsteadiness of baseline with a single fusion beat, 2) ventricular premature beats two minutes later, and 3) paroxysms of ventricular tachycardia.

vestigated dogs with normal hearts. When a dog was placed in a sling where it had received an electrical shock the previous day, its threshold for repetitive extrasystoles was 40%–50% lower than when it was in the tranquil environment of the cage. This difference in response indicates increased vulnerability to fibrillation in the presence of increased stress (9–12). These studies also documented that the onset of increased vulnerability was extremely rapid, occurring within a few minutes of exposure to stress. On the other hand, restoration of control conditions after withdrawal from stress required a much longer time (12). This is consistent with clinical observations relating to latency of the cardiac response and recovery when an individual is subjected to psychologic stress.

Similar findings have been reported by Skinner and associates (15), who studied the effects of familiar and unfamiliar environments on the occurrence of ventricular fibrillation caused by acute coronary occlusion in pigs. In the unfamiliar setting fibrillation occurred a few minutes after the induction of coronary occlusion. When the same experiment was performed in an environment to which the pigs had previously adapted, onset of fibrillation was greatly delayed and even entirely prevented in some animals. We have found also that a shock avoidance paradigm in dogs markedly lowered the threshold for ventricular fibrillation (10). Thus a variety of psychologic stresses induce profound changes in cardiac electrophysiologic properties that favor the development of ventricular fibrillation.

Neural Mechanisms

It is pertinent to consider the neural mechanisms by which psychologic stresses lower the ventricular vulnerable period threshold and predispose to ventricular fibrillation. The mammalian ventricle is richly innervated by the autonomic nervous system. Both the sympathetic and the parasympathetic divisions are represented. A large number of studies spanning a hundred years indicate that cardiac electrical activity is influenced by neural inputs (5). Stimulation of peripheral nerve structures such as the cardiac sympathetic nerves and the stellate ganglia increases susceptibility to ventricular fibrillation. Earlier in this century it was shown that injection directly into the brain of drugs or chemicals such as nicotine, barium chloride, caffeine, epinephrine, acetyl choline, and strophanthidin produced ventricular arrhythmias including fibrillation. Subsequent studies using more precise methods with the aid of stereotaxically placed electrodes demonstrated the occurrence of ventricular arrhythmias during stimulation of the frontal, orbital, motor and premotor cortical areas, the anterior part of the temporal lobe, the insula, and the cingulate gyrus. Korteweg and colleagues (16) found that arrhythmias were more readily provoked from subcortical areas such as the posterior hypothalamus and the quadrigeminal bodies.

Myocardial ischemia is the most potent predisposing factor for the development of ventricular fibrillation. Satinsky and coworkers (17) studied the effect of stimulation of the cardiac accelerator and vasomotor centers in the posterior hypothalamus during acute myocardial ischemia in anesthetized dogs. Stimulating electrodes were stereotaxically placed in the hypothalamus. In the absence of hypothalamic stimulation, during ligation of the left anterior descending coronary artery only 2 of the 32 dogs (6.3%) developed ventricular fibrillation. This low incidence of ventricular fibrillation was increased ten-fold to 62.5% when the hypothalamus was stimulated immediately after acute ischemia was induced by ligation of the same vessel. This study indicated that the profibrillatory effect of myocardial ischemia can be potentiated by neural traffic originating in hypothalamic nuclei. The pathway through which cortical and subcortical inputs affect the heart is likely to be the sympathetic nervous system since susceptibility to ventricular arrhythmias is ablated by cardiac sympathectomy or sympathetic blockade with beta-adrenergic blocking drugs (4). Also, stimulation of stellate ganglia replicated the results obtained with midbrain stimulation even in experiments wherein blood pressure and heart rate effects of enhanced sympathetic activity were precluded (18, 19).

Are sympathetic-adrenergic mechanisms also implicated in the susceptibility to ventricular fibrillation resulting from psychologic stress? Animals trained to avoid programmed electric shock showed a 50% re-

duction in repetitive extrasystole threshold persisting throughout the three days in which they were exposed to this biobehavioral stress (10). However, when the animals received intravenously the beta-1 cardioselective drug Tolamolol in doses sufficient to annul the heart rate response to isoproterenol, the change in cardiac vulnerability for repetitive response was prevented. Thus, beta-adrenergic blockade, which inhibits the effects of sympathetic autonomic discharge, obviated the changes in cardiac vulnerability induced by instrumental aversive conditioning.

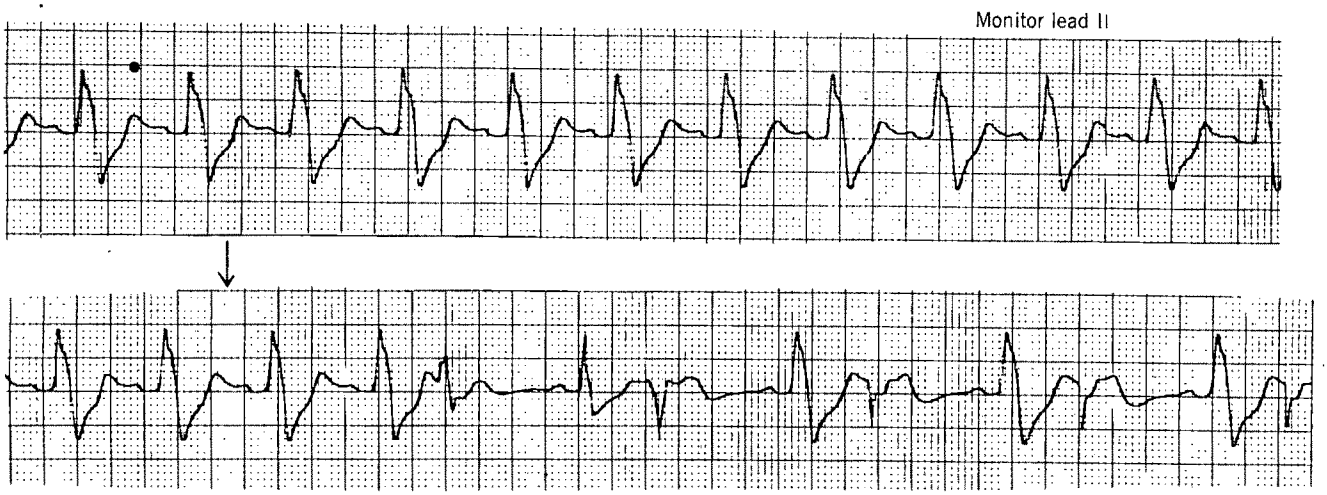
There has been less clarity about the role of the parasympathetic nervous system in the genesis of ventricular arrhythmias. The investigations of Richter (20) have exerted profound influence in directing psychologic investigators to the vagus as a cause of sudden death. Rats made to swim in water tanks died from bradycardia and asystole rather than from ventricular fibrillation or from drowning, and the mechanism was believed to be enhanced vagus nerve activity. While the simple faint in man is caused by this means, sudden cardiac death is largely the result of ventricular fibrillation. In fact, experimental evidence (21–29) argues a converse thesis, namely that the vagus exerts antiarrhythmic action on the ventricular myocardium. The protective effect of the vagus is demonstrable only in the presence of enhanced adrenergic drive, whether elicited by stellate ganglion stimulation (28) or catecholamine infusion (29). That the action of the vagus depends on increased sympathetic tone is further indicated by the observation that when beta-adrenergic blockade was induced, changes in ventricular excitability (30) and vulnerability (28) were completely precluded. The antiarrhythmic vagal effect is due to its muscarinic properties and can be annulled by atropine (29).

Thus, the vagus nerve exerts but an indirect action on cardiac vulnerability by antagonizing augmented sympathetic tone. The basis for the cholinergic antagonism is due to muscarinic stimulation that inhibits the release of norepinephrine from sympathetic nerve endings and attenuates the response to catecholamines at receptor sites. Vagal afferent activity also exerts a protective influence on vulnerability by tonic inhibition of sympathetic neural discharge. These mechanisms also operate in the conscious state and modulate ventricular electrical stability in response to psychophysiologic stimuli (31).

Neurochemical Aspects

Sympathetic and parasympathetic neural activity continuously modulate the excitable properties of the heart. It may therefore be worthwhile to probe the role of brain neurotransmitters in the generation of autonomic neural traffic that affects cardiac vulnerability to ventricular fibrillation. This approach is especially inviting in view of the seminal investigations of Wurtman and Fernstrom (32, 33), which indicate that neurotransmitter synthesis in the brain can be modified by dietary means.

There is evidence that accumulation of serotonin in the brain may reduce sympathetic neural activity (34, 35). It has been demonstrated that concentration of central serotonin depends on plasma levels of tryptophan, the essential dietary amino acid and the physiologic biochemical precursor of serotonin. When tryptophan alone is administered, it is hydroxylated and then decarboxylated to form serotonin throughout the body (36). Monoamine oxidase then catalyzes a rapid degradation of serotonin. However, serotonin can be concentrated in the brain by following tryptophan administration with the simultaneous monoamine oxidase inhibitor phenelzine and the L-aromatic amino acid decarboxylase inhibitor carbidopa. Phenelzine crosses the blood barrier and favors the accumulation of serotonin wherever it is formed. However, carbidopa is limited to the peripheral circulation and thereby restricts serotonin formation to the brain.



Rabinowitz and Lown (37) used these methods to determine their effect on cardiac susceptibility to repetitive extrasystoles, which is a measure of ventricular vulnerability to fibrillation. When tryptophan, phenelzine, and carbidopa were given separately no change in ventricular threshold for repetitive response was noted. However, a sustained increase of 50% in this threshold resulted from the use of biochemical measures that presumably increase serotonin levels in the central nervous system. When 5-hydroxytryptophan was administered instead of its parent compound tryptophan, thus bypassing the rate-limiting step of hydroxylation, the threshold increased within one hour, compared to 2½ hours after tryptophan.

A further corroboration of the above observations is provided by the recent findings of Blatt and coworkers (38). Systemic administration to dogs of the three central serotonergic agents, including melatonin, induced significant increases in the threshold of the ventricular vulnerable period for repetitive myocardial electrical activity. Such changes were blocked by the specific serotonin antagonist metergoline. These findings have significant clinical implications. Modern neuropharmacology is providing agents that enable precise alterations in brain neurochemistry and thereby permit elicitation of discrete cardiovascular effects. This approach may provide a new method for reducing ventricular vulnerability to fibrillation by neuropharmacologic measures.

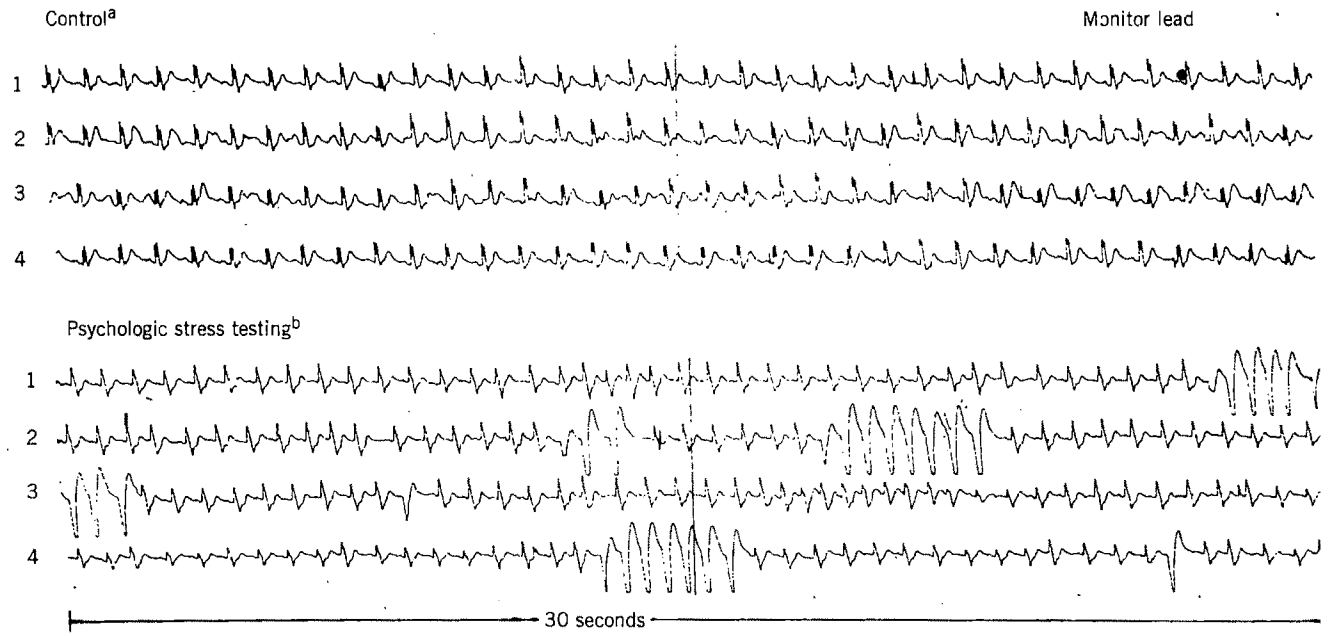
CLINICAL STUDIES

While one may design adequate animal models to simulate biologic problems in man, the ultimate validation of putative causal connections requires direct investigation of the human condition. That emotions

FIGURE 2
Ventricular Arrhythmia in a Woman with Previous Ventricular Fibrillation When Conversation Was Shifted to Domestic Conflict (arrow)[a]

[a]The conversation occurred 48 hours after the woman had been resuscitated from ventricular fibrillation. She had been entirely free of ventricular arrhythmia during continuous monitoring in a coronary care unit, but when, during the fourth minute of conversation, the topic was shifted to domestic conflict with her family, ventricular bigeminy with T-wave interruption emerged and persisted until the discussion was shifted to less psychologically aversive content. This arrhythmic response was consistently reproducible.

play a role in sudden death has gained currency by repetition if not by precise documentation. The role of psychologic and emotional factors in the provocation of sudden death is chronicled in the earliest folklore of diverse cultures. Engel (39) has compiled anecdotal reports gleaned from the daily press of 170 sudden deaths that occurred in association with profound emotions such as bereavement, real or symbolic danger, loss of status, and even joy. However, such a conjunction of events, while compelling attention and speculation, is but meager evidence of causality.



The problem can be approached more readily by considering the antecedent mechanisms that predispose to ventricular fibrillation, the underlying basis for sudden cardiac death. The hypothesis that certain complex forms of ventricular ectopic (or premature) beats may portend sudden fatality among patients with ischemic heart disease (1, 6) has now been confirmed in extensive epidemiologic and clinical investigations (40–45). It is thus inviting to examine interactions between psychologic factors and the occurrence of ventricular arrhythmias that may predispose to sudden death. The study of arrhythmias affords several advantages over investigating other disease states. The deranged heart rhythm is directly exposed by electrocardiographic monitoring, is sporadic and recurrent, and has a precise time of onset and offset. These factors not only simplify appreciation of end-organ changes but provide opportunity for defining possible causal connections between psychologic stresses and occurrence of arrhythmia.
